For my parents

Summary

The RecQ DNA helicases are highly conserved from bacteria to man and are required for the maintenance of genomic stability. All unicellular organisms contain a single RecQ helicase, whereas the number of RecQ homologues in higher organisms can vary. Mutations in the genes encoding three of the five human members of the RecQ family give rise to autosomal recessive disorders called Bloom syndrome, Werner syndrome and Rothmund-Thomson syndrome. These diseases manifest commonly with genomic instability and a high predisposition to cancer. However, the genetic alterations vary as well as the types of tumours in these syndromes. Furthermore, distinct clinical features are observed, like short stature and immunodeficiency in Bloom syndrome patients or premature ageing in Werner Syndrome patients. Also, the biochemical features of the human RecQ-like DNA helicases are diverse, pointing to different roles in the maintenance of genomic stability.

The goal of my thesis was to explore the functions of the human RecQ homologues BLM, WRN and especially the so far biochemically uncharacterised RECQ5, with a focus on the identification of functional domains of these proteins, their biochemical properties and modes of action.

To characterise the domain organisation of the BLM protein, Janscak *et al.* (1) purified from *E. coli* and biochemically characterised a deletion variant of BLM, encompassing amino acids 642-1290. This truncated version contained the DEAH, the RecQ-Ct and the HRDC domains. This fragment was proficient in DNA-stimulated ATPase and DNA helicase activity displaying the same substrate specificity as the full-size protein. Gel-filtration experiments revealed that it exists as a monomer in solution both free and in its DNA-bound form, even in the presence of Mg^{2+} and ATP- γ S. With a λ Spi⁻ assay, it could be shown that BLM⁶⁴²⁻¹²⁹⁰ is able to partially suppress the illegitimate recombination in *E. coli* *recQ*⁻ strains. Furthermore, the RecQ-Ct domain was identified as a region essential for activity of the protein, and the HRDC domain as an auxiliary DNA binding domain.

With my work on RECQ5 β (2), I could show the first biochemical characterisation of this RecQ DNA helicase. After overexpression in *E. coli*, I purified the protein to high homogeneity and subjected it to various biochemical assays. The protein showed the predicted ATP-dependent 3'-5' helicase activity and was also able to promote the

migration of Holliday junctions. Surprisingly, RECQ5 β displayed a DNA strand-annealing activity residing in the C-terminal half of the protein. This activity was strongly inhibited by RPA. Inhibition of the annealing activity could also be observed in the presence of the poorly hydrolysable ATP γ S, which was alleviated by mutations in the ATP binding motif of RECQ5 β , indicating an inability of RECQ5 β to anneal DNA strands in the ATP-bound form.

BLM and WRN are classified as SF2 helicases and show ATPase activity with single and double stranded DNA as effectors, indicating that translocation along the DNA is mediated by contacts with the phosphodiester backbone. SF1 helicases like the PcrA from *B. stearothermophilus* make contacts with the bases of the DNA, which is dependent on the rotational flexibility of the DNA backbone. I have shown that DNA unwinding by BLM and WRN was inhibited by vinylphosphonate internucleotide linkages in the DNA that reduce the rotational flexibility of the phosphodiester backbone; an effect also observed with PcrA (3). However, in contrast to PcrA, a single stranded DNA binding protein RPA could alleviate the inhibitory effect of these modifications on BLM and WRN-mediated unwinding, pointing to mechanistic differences between SF1 and SF2 helicases.

One of the functions of BLM is to act together with Topoisomerase III α to process recombination intermediates containing double Holliday junctions using a strand-passage mechanism that prevents the formation of cross-over products (4). Wu *et al.* (5) have shown that this dissolution reaction is highly specific to BLM amongst the human RecQ helicases and that it requires the HRDC domain of BLM. The HRDC domain is essential for the efficient binding to and unwinding of double Holliday junctions by BLM. The unwinding of simple duplexes is not an activity of the protein that is required for this reaction. The lysine 1270 of BLM located in the HRDC domain is required for efficient dissolution and is predicted to majorly contribute to the interaction with DNA.

Cheok *et al.* have shown that, in addition to the highly conserved DNA unwinding activity, BLM also contains a strand-annealing activity that does not require Mg²⁺, is inhibited by ssDNA binding proteins and ATP, and is dependent on DNA length. Through deletion analysis we have shown that a 60 amino acid stretch in the C-terminal part of BLM is important for strand annealing (6).

Zusammenfassung

Die RecQ DNS Helikasen sind hochkonserviert in Bakterien bis zum Menschen und sind wichtig für die Bewahrung genomischer Stabilität. Alle unizellulären Organismen beinhalten eine einzige RecQ Helikase, während die Anzahl in höheren Organismen variieren kann. Mutationen in drei der fünf menschlichen RecQ-Homologen resultieren in den seltenen autosomal rezessiven Krankheiten Bloom Syndrom, Werner Syndrom und Rothmund-Thompson Syndrom. Diese Krankheiten zeichnen sich alle durch genomische Instabilität und hohe Krebsdisposition aus. Jedoch zeigen Syndrome Unterschiede bezüglich der genetischen Veränderungen, Art der Tumore und klinischen Befunden. Die biochemischen Eigenschaften der humanen RecQ DNS Helikasen sind auch verschieden, auf deren unterschiedlichen Aufgaben in verschiedenen Ketten und Rollen in Gewährleistung der genomischen Stabilität hinweisend.

Das Ziel meiner Dissertation war es, die Funktionen der RecQ Homologen BLM, WRN und besonders die des bis dahin spärlich charakterisierten RECQ5 zu erforschen mit speziellem Augenmerk auf die Identifikation funktioneller Domänen, biochemische Eigenschaften und Reaktionsmechanismen.

Um die Domänorganisationsstruktur des BLM Proteins zu definieren, haben Janscak *et al.* (1) eine Deletionsvariante von BLM, das Peptid der Aminosäuren 642-1290, nach Überexpression in *E. coli* aufgereinigt und biochemisch charakterisiert. Die Variante enthält die DEAH Helikasen-, die RecQ-Ct und die HRDC Domänen. Dieses Fragment zeigte DNS-stimulierte ATPase Aktivität mit derselben Substratspezifität wie das Protein der ganzen Länge. Durch Gel-filtrationsexperimente konnte gezeigt werden, dass das Protein in Lösung frei und in DNS gebundener Form als Monomer vorlag, was nicht durch die Präsenz von Mg^{2+} sowie von $ATP\gamma S$ beeinflusst wurde. In einem λ Spi Versuch hat sich gezeigt, dass $BLM^{642-1290}$ partiell die illegitime Rekombination in *E. ColiRecQ⁻* unterdrücken konnte. Des Weiteren wurde die RecQ-Ct Domäne als eine für die Aktivität des Proteins essentielle Region und die HRDC Domäne als auxiliäre Bindungsdomäne identifiziert werden.

Durch meine Arbeit mit RECQ5 β , konnte ich die erste biochemische Charakterisierung dieser RecQ-ähnlichen DNS Helikase zeigen (2). Nach Überexprimierung in *E. coli* habe ich das Protein zu hoher Homogenität aufgereinigt und es mittels klassischen Helikasenversuchen charakterisiert. Das Protein hat die vorausgesagte ATP-abhängige

3'-5' Helikasenaktivität gezeigt, und vermochte auch Holliday Strukturen zu migrieren. Erstaunlicherweise zeigte dieses Protein eine DNS-Paarungsaktivität im C-terminalen Teil, welche durch RPA inhibiert werden konnte. Die Inhibition der Paarungsaktivität konnte ebenfalls durch das schwach hydrolysierbare ATP γ S beobachtet werden, was wiederum durch Mutationen im ATP-Bindungsmotiv aufgehoben wurde, darauf hindeutend, dass das Protein in ATP-gebundener Form nicht in der Lage ist, DNS Stränge aneinanderzuführen.

BLM und WRN sind als SF2 Helikasen klassifiziert und zeigen ATPase Aktivitäten mit einzelsträngiger sowie doppelsträngiger DNS als Effektoren, auf einen Translokationsmechanismus deutend, welcher durch Kontakte mit dem Phosphodiestergerüst bewerkstelligt wird. SF1 Helikasen wie PcrA aus *B. stearothermophilus* gehen Kontakte mit den Basen ein, was eine Rotationsflexibilität der DNS benötigt. Ich konnte zeigen, dass die Helikasenaktivität von BLM und WRN durch den Einbau von Vinylphosphonaten, welche die Rotationsflexibilität des Phosphodiestergerüsts der DNS vermindern, inhibiert wurde; ein Effekt, der auch mit PcrA beobachtet wurde (3). Im Gegensatz zu PcrA konnte der inhibitorische Effekt durch das humane einzelstrangbindende RPA aufgehoben werden, auf mechanistische Unterschiede zwischen SF1 und SF2 Helikasen hindeutend (3).

Eine der Funktionen von BLM ist, Rekombinationsintermediate mit doppel Holliday Strukturen zusammen mit TOPOIII α aufzulösen (4) um die Entstehung von "cross-over"-Produkten zu verhindern. Wu *et al.* (5) haben gezeigt, dass diese Reaktion, im Englischen "double Holliday junction dissolution" genannt, hochspezifisch für BLM ist unter den humanen RecQ Helikasen und dass die HRDC Domäne von BLM benötigt. Wir konnten des Weiteren zeigen, dass die HRDC Domäne von BLM essenziell fuer die Bindung an und Aufwindung von doppel Holliday Strukturen ist. Das Aufschmelzen simpler DNS Duplexe ist nicht eine Aktivität, welche für diese Reaktion benötigt wird. Lysin 1270 in BLM ist wichtig fuer die effiziente Dissolution und scheint einen wichtigen Beitrag zur Interaktion mit der DNS zu leisten.

Cheok *et al.* haben gezeigt, dass BLM, zusätzlich zu der hochkonservierten Helikasenaktivität, eine DNS-Basenpaarungsaktivität besitzt. Diese durch BLM bewerkstelligte Basenpaarung ist Mg²⁺-unabhängig, wird durch einzelsträngige DNS inhibiert und ist von der DNS-Länge abhängig. Durch Deletionsanalyse konnte gezeigt werden, dass die C-Terminale Domäne dafür essenziell ist, und 60 Aminosäuren davon für die

Bindung einzelsträngiger DNS und für die Basenpaarung wichtig ist (6).

1 Helicases - Classification and Mode of Action

Helicases are ubiquitous enzymes that use the free energy from NTP hydrolysis to separate the two component strands of double-stranded nucleic acids (DNA-DNA, RNA-DNA, RNA-RNA). These enzymes play essential roles in all aspects of nucleic acid metabolism (7).

Helicases are classified according to sequence homology and directionality. The directionality is defined with respect to the nucleic acid strand on which the enzyme translocates (3'-5' or 5'-3') (8). Based on amino acid sequence homology, helicases are classified into five major groups, denoted superfamilies 1-5 (SF1-5) (Table 1). SF1 and SF2 are the largest and are characterised by a set of similar amino acid motifs called Q, I, Ia and II-VI (Figure 1). SF3 helicases harbour only three different conserved helicase motifs called A, B and C and the SF4 helicases are known to have the five motifs called 1, 1a and 2-4 (9). The motifs of the SF5 members have not been well described.

Table 1: Classification of Helicases based on sequence homology, with some examples.

Figure 1: Schematic representation of the domain organisation of the DEAD box helicases. boxes represent conserved helicase motifs showing consensus sequences by single-letter amino acid code. (Z=D, E, H, K, R; O=S, T; X=any aa). Adapted from Ref. (14).

In Figure 1, the domain organisation of DEAD box helicases is schematically depicted. The Q-motif is characteristic of the DEAD box family (15; 16). It contains a highly conserved glutamine which is also present in the "Q" motif of the RecQ helicases that belong to the DExH helicase family. In *E. coli* RecQ the conserved glutamine has been shown to bind to the adenine moiety of the ATP cofactor (17). For a number of helicases it has been shown by mutational analysis that this conserved residue is essential for ATPase and helicase activity of the enzyme. Moreover, a missense mutation at the equivalent residue of the BLM helicase is sufficient to cause the Bloom syndrome (18). Motif I is also referred to as the Walker A motif found in ATPases (19). This domain is also essential for ATP binding; a conserved lysine residue makes contacts with the β and the γ phosphates of the ATP molecule (20). The motif Ia has been shown to contribute to ssDNA binding in the UL9 helicase from the Herpes Simplex Virus (HSV) and is present in many SF1 and SF2 helicases (21). In the DEAD and DExH helicases an additional motif named Ib motif is found with a consensus sequence of TxGx (14). Motif II is equivalent to Walker B motif also found in other ATPases. Based on the sequence of this motif, helicases are further classified into the DExH and the DEAD families. The highly conserved aspartate residue in Motif I (D of DE) coordinates Mg^{2+} , and is required for ATP hydrolysis but not binding (20). Motif III is very likely to be important for coupling ATPase to helicase activity (22). Motif IV seems to be essential for the later steps of the ATPase reaction as it binds ADP. Motif V is likely to serve as an additional domain for binding DNA, since it has been shown to make contacts with the sugar-phosphate backbone (9). The motif VI has been proposed to be required for the helicase to move along the DNA substrate by mediating conformational changes associated with nucleotide binding (14).

For the mode of action of helicases, several models have been proposed and are depicted schematically in Figure 2. In the inchworm model, the enzyme binds to ssDNA and translocates along the strand until it reaches the duplex which is then invaded and unwound (23). The modified inchworm model has been proposed for the monomeric UvrD helicase. The enzyme consists of two DNA binding subdomains, a leading domain that binds to ssDNA and dsDNA and a trailing domain that only binds to ssDNA. ATP binding induces a closed conformation of the enzyme by pulling the trailing domain towards the leading domain. Upon ATP hydrolysis, the trailing domain remains on ssDNA and the leading domain is moved forward into the duplex and mediates strand

separation (24; 25). In the active rolling model, the helicase consists of two identical subunits that can both bind to ssDNA and dsDNA. One subunit stays bound on ssDNA and the subunit behind will detach from the DNA and rotate around the bound subunit to bind dsDNA. A conformational change upon ATP hydrolysis will then lead to the separation of the duplex (26).

Figure 2: Models for DNA helicase translocation and unwinding. (A) Inchworm model. (B) Modified inchworm model. Leading domain in green, trailing domain in blue. (C) Active rolling model. Two identical subunits in green and purple.

2 The RecQ Family of DNA Helicases

2.1 General Features and Structural Organisation

The RecQ helicases, named after the DNA helicase RecQ of *Escherichia coli*, are highly conserved from bacteria to man. Defective functions of these proteins lead to genomic instability that generally manifests as hyperrecombination. In humans, defects in the *BLM*, *WRN* and *RTS/RECQ4* genes are associated with the autosomal recessive, cancer-prone diseases Bloom syndrome (BS) (27; 28), Werner syndrome (WS) (29; 30) and Rothmund Thompson syndrome (RTS) (31; 32; 33), respectively. Higher organisms contain several RecQ homologues, with five homologues identified in humans. These proteins presumably play specialised roles in genome maintenance since distinctions in the clinical as well as the cellular manifestations of BS, WS and RTS have been observed. Furthermore, the multiple RecQ homologues also display differences at the biochemical level with overlapping, but also very distinct substrate specificities mostly due to the presence of various additional functional domains. The diverse protein interaction partners observed further implicate different human RecQ homologues in different DNA transactions. It seems that the cellular functions of the sole RecQ homologues in unicellular organisms are divided up into and extended on several homologues in higher organisms.

Figure 3: Schematic representation of the RecQ helicases of selected organisms. The domains of the RecQ from *E. coli* are labelled; helicase domains in red and blue, Zinc-binding domain in yellow, the winged helix domain in green and the HRDC domain in purple, according to the crystal structure of the *E. coli* RecQ helicase (34). The putative nuclear localisation signals (NLS) are marked by red boxes. WRN contains an additional exonuclease domain and a direct repeat (blue triangles). The lengths of the proteins are given to the right in number of amino acids.

In Figure 3, selected RecQ helicases are drawn schematically. All RecQ members contain the helicase domains characteristic of the DEAH subgroup of SF2 helicases (10). The adjacent Zn^{2+} binding domain has been found in all RecQ helicases examined, except for RECQ4. Another characteristic of the RecQ members is the winged helix (WH) domain, which has only been found to be absent in the human RECQ4 and RECQ5 and their orthologues. Furthermore, distal to the WH domain, the Helicase and RNase D C-terminal (HRDC) domain is found. This domain is absent in RECQ1, RECQ4 and REQ5. The WRN helicase contains an additional 3'-5' exonuclease at the aminotermius of the protein and a 27 amino acid repeat between the exonuclease and the helicase domains. All unicellular organisms examined contain a single RecQ homologue that harbours all the common conserved motifs, such as the helicase domains, the Zn^{2+} binding domain, the WH domain and the HRDC domain (34).

Some biochemical characteristics of selected members of the RecQ family are listed in Table 2. Figure 4 schematically shows some substrates that have been used to study

the substrate specificities of RecQ helicases in Table 2.

	Blunt-ended duplex Enzymes that require a free ssDNA tail or load to a specific structure do normally not unwind such a structure by themselves.
	5'-tailed duplex A substrate for 5'-3' helicases that load on free ssDNA or to the ssDNA/dsDNA interface.
	3'-tailed duplex A substrate for 3'-5' helicases that load on free ssDNA or to the ssDNA/dsDNA interface.
	Duplex containing a bubble This substrate mimicks a duplex with a distortion of the helix or DNA containing a loop.
	Splayed arm or forked duplex 5'-3' and 3'-5' helicases that require free ssDNA or load on this specific junction will unwind such a substrate.
	A classic helicase substrate Large circular ssDNA containing a partial duplex. This substrate has been mostly prepared from M13 ssDNA annealed to a synthetic oligonucleotide
	D-loop structure This substrate mimicks an intermediate from homologous recombination, a ssDNA strand invades the duplex to form this structure. Disruption of D-loops can be monitored if the enzyme does not unwind from blunt ends.
	Holliday junction or 4-way junction A synthetic Holliday junction resulting from annealing of four oligonucleotides. Used to test for Holliday junction branch migration. A preferred substrate for BLM.
	G4 DNA, also called G quadruplex DNA. G-rich sequences, especially at telomeres, can form such a structure through Hoogsteen-bonds between Gs. This structure is biochemically formed from one oligonucleotide and is stable at room-temperature. A preferred structure for BLM, WRN and Sgs1.

2.2 The *Escherichia coli* RecQ

2.2.1 Genetics

The RecQ protein from *Escherichia coli* is the founding member of the RecQ DNA helicase family and was discovered in 1984 by Nakayama *et al.* in a screen for mutations that confer resistance to thymineless death (68; 69). RecQ acts in the RecF pathway of homologous recombination that operates in the repair of stalled replication forks. RecQ mutations in a *recBC sbcB* background lead to an enhanced UV sensitivity and lower the efficiency of conjugal recombination (68). RecQ and RecJ are required for lagging strand degradation at stalled replication forks. (70; 71; 72). RecQ is involved in the suppression of illegitimate recombination, which is enhanced 30-300 fold in *recQ*⁻ mutants (73). A recent study shows that RecQ is needed for the fast degradation of the LexA repressor in response to UV irradiation to induce the SOS response (74), reviewed in Ref. (75). The SOS response is a mechanism of bacteria strongly enhanced by the formation of RecA filaments and induces the expression of roughly 30 DNA repair genes as a response to DNA damage (76).

2.2.2 Biochemical Properties of RecQ

The *RecQ* gene codes for a 610 amino acids long protein that is an ATP-dependent 3'-5' helicase. In an initial biochemical characterisation of RecQ, Umezu *et al.* observed that the protein is able of unwinding partial duplexes as long as 143 bp in an ATP-dependent manner (40). Harmon and Kowalczykowski found that RecQ is capable of unwinding a wide variety of abnormal DNA structures including D-loops, indicative of a role in suppressing illegitimate recombination by disrupting aberrant recombination intermediates (42). Furthermore, RecQ was shown to unwind a covalently closed double-stranded DNA substrate which can activate the strand-passage activity of DNA topoisomerase III (77). Further biochemical properties are in another chapter (Chapter 2).

2.2.3 Models for RecQ-mediated DNA Transactions

Based on genetic and biochemical evidences, four roles for RecQ in the maintenance of genomic stability in *E. coli* have been proposed (Figure 5): In a model for the initiation of recombination, RecQ unwinds DNA at gaps (in wt cells) or double-strand breaks

(in *recBC⁻* cells) allowing RecA filament formation to initiate recombination and D-loop formation (42). In the anti-recombination model, RecQ can disrupt D-loops formed by RecA (42). RecQ is very likely to perform the double Holliday junction (DHJ) dissolution, as it has been shown that RecQ in concert with Topo III can catenate/decatenate duplex DNA (77), and that BLM together TOPOIII α can perform the DHJ dissolution (4) it is likely that RecQ can, together with Topo III perform this reaction as well *in vivo*. In the SOS model of Hishida *et al.* (74), RecQ binds a gap on the leading strand of a stalled replication fork and unwinds the duplex template ahead of the fork, in a 3'-5' direction. The ensuing topological stress may be relieved by the combined action with a type I topoisomerase such as Topo III. Subsequently, RecQ switches to the lagging strand template, generating a single-stranded DNA gap on the lagging strand, on which a RecA filament is assembled in the 3' direction, leading to SOS induction. Subsequent repair of the blocking lesion, trans-lesion synthesis, or recombinational restart may lead to the resumption of DNA replication.

Figure 5: Roles of the RecQ DNA helicase in genomic maintenance. Adapted from Ref. (75) (A) Initiation of recombination. (B) Anti-recombination. (C) DHJ dissolution. (D) The SOS model.

2.2.4 Structure of RecQ

Bernstein and Keck have crystallized the catalytic core of the *E. coli* RecQ protein and resolved its structure (34). The crystal structure of RecQ is shown in Figure 6. In this work, the authors show that C-terminally adjacent to the helicase domains, there are two additional structural motifs that are not present in other helicases: The Zn^{2+} -binding domain contains four highly conserved cysteines which coordinate a zinc ion. Adjacent to that lies the winged helix (WH) domain forming a helix-turn-helix fold, found to act as a DNA binding motif in many proteins (78). The HRDC was not present on the polypeptide crystallized and its function is not yet fully elucidated. Liu *et al.* have resolved the 3-dimensional structure of the HRDC of Sgs1 from *Saccharomyces cerevisiae*, but were not able to draw functional conclusions from this work (79).

Recently, Liu *et al.* have characterised the importance of the Zn^{2+} -binding domain. They show that the highly conserved cysteines form a complex with the Zn^{2+} . This complex is essential for DNA binding and helicase activity, but not for ATP binding. Furthermore, they show that this zinc finger binding motif is important in maintaining the integrity of the protein structure. They further discuss that this Zn^{2+} finger is unique to the RecQ family (80).

Figure 6: The structure of the RecQ catalytic core. Adapted from Ref. (34). (A) Schematic diagram of *E. coli*. Three conserved regions, helicase, RecQ-conserved (RecQ-Ct), and Helicase-and-RNase-D-C-terminal (HRDC) (81), are labelled. The catalytic core of *E. coli* RecQ (RecQ Δ C) includes only the helicase and RecQ-Ct regions, and comprises four apparent subdomains in the structure: residues 1-208 in red, 209-340 in blue, 341-406 in yellow and 407-516 in green. (B) Sequence and secondary structure of RecQ Δ C. Helices (boxes) and β -strands (arrows) are shown above the sequence and labelled sequentially. Colour coding is the same as in (A). Conserved helicase motifs (motifs 0-VI) are labelled and enclosed in boxes. Residues that are invariant among 65 bacterial RecQ proteins are underlined, and residues that are invariant or highly conserved with a subset of eukaryotic RecQ proteins (human WRN, BLM, and *S.cervisiae*) are highlighted in purple or light-blue boxes, respectively. (C) Orthogonal views of a ribbon diagram of the crystal structure of RecQ Δ C, colour-coded as in (A). A bound Zn²⁺ ion is shown as a magenta sphere.

2.3 *Saccharomyces cerevisiae* Sgs1

2.3.1 Sgs1 Cellular Phenotype

Sgs1 was identified as a suppressor of the slow growth phenotype of *top3* mutants (Chapter 2.3.3). *sgs1* mutant budding yeast cells show a 40% decrease in lifespan compared to wild-type cells (82; 83). McVey *et al.* have shown that *sgs1* mutants in fact arrest in G_2 or in G_1 (84). *sgs1* mutants do not show differences in telomere lengths, compared to wild-type cells (85), but the double mutants *sgs1 tlc1* and *sgs1 est2* show an elevated rate of telomere shortening compared to the single *tlc1* mutant, indicating a role in telomere maintenance (86). *sgs1* cells show increased sensitivity to treatment with MMS (87; 88), UV light (89; 90) and HU (91), but not to γ -radiation (91). At the chromosomal level, *sgs1* mutants display a wide variety of defects as marker loss (85; 92), an elevated rate of sister chromatid exchanges (SCE) (93), gross chromosomal rearrangements (94; 95), a higher rate of loss of heterozygosity (96) and an increased level of illegitimate recombination (97). MMS-induced interchromosomal recombination was found to be reduced in *sgs1* cells and UV light exposure of these mutants only induced little of those events (92).

2.3.2 Biochemical Properties of Sgs1

Sgs1 codes for a protein of 1447 amino acids and has not been purified at the full length yet. Biochemical assays were performed with a deletion variant *Sgs1*⁴⁰⁰⁻¹²⁶⁸, which is as the other RecQ helicases an ATP-dependent 3'-5' helicase being able to unwind a wide variety of abnormal DNA structures including Holliday junctions (HJ) and D-loops (Chapter 2). Not only is *Sgs1* able to unwind DNA duplexes, it can also disrupt RNA/DNA hybrid molecules (60).

The abundance of *Sgs1* is cell-cycle regulated, with low levels in M and G_1 , a peak in S and degradation in G_2 . *Sgs1* forms S-phase specific nuclear foci which partially co-localise with Rad53 and the origin recognition complex (82). Sinclair *et al.* have reported *Sgs1* to localise into the nucleolus (82), while Frei and Gasser did not observe this (91).

2.3.3 Interaction Partners and Models for DNA Transactions

Topoisomerases

DNA topoisomerases are enzymes that alter the state of supercoiling of DNA by a strand-passage mechanism involving transient DNA breaks. According to their mode of action, they are classified into the type I topoisomerases which generate ssDNA breaks and into type II topoisomerases that create dsDNA breaks to mediate strand-passage.

The *S. cerevisiae* *Sgs1* was identified by three different groups independently, but always in the context of either a topoisomerase gene or protein. Gangloff *et al.* discovered *Sgs1* in a screen for suppressors of the *top3* slow-growth phenotype (98). Watt *et al.* identified *Sgs1* in a search for interaction partners of Top2 (99) and Lu *et al.* found *Sgs1* because of genetic interaction with Top1 (Type I) (100). *Sgs1* interacts physically and genetically with all three nuclear topoisomerases. Yeast Top1 is required for DNA replication (101), mitotic chromosome condensation (102) and general transcriptional repression in stationary phase (103). Under normal conditions, a deletion of *top1* has no effect on growth. Top1 has been reported to interact with *Sgs1*, but the role of this complex has not been identified yet (99; 82). Top2 (Type II) is required for the resolution of intertwined chromosomes during mitosis and meiosis and is an essential gene (104; 105; 106). Genetically, *Top2* and *Sgs1* have been reported to be epistatic with regard to reducing chromosome non-disjunction, suggesting that they are involved in the same pathway for chromosome segregation (85).

Top3 mutants grow poorly (107; 108), are sensitive to DNA damaging agents (109; 110), have severe meiotic defects (111; 112) and exhibit hyper-recombination between repetitive sequences such as telomeres and rDNA (101; 108; 111). The G₂ delay, elevated frequency of marker loss and altered morphology of a *top3* mutant are suppressed by mutations in the *Sgs1* gene (98; 113). Recombinant Top3 (Type I) only acts on negatively supercoiled dsDNA (107). Ira *et al.* have shown that the deletion of *Sgs1* increases crossovers in yeast cells 2-3 fold. The overexpression of *Srs2* nearly eliminates crossovers, whereas overexpression of *Rad51* in *srs2* cells almost completely eliminates the noncrossover recombination products. It is very likely that *Sgs1* in concert with Top3 performs the same reaction as BLM/TOPOIII α on DHJs.

Sgs1 and Homologous Recombination

Srs2 is a 3'-5' helicase showing only limited homology to the *E. coli* UvrD helicase and no homology to any known human protein (114). Srs2 suppresses homologous recombination (HR) through disrupting Rad51 ssDNA filaments (115; 116). Recently, Pfander *et al.* have demonstrated that SUMO-modified PCNA recruits Srs2 in S phase to prevent unwanted recombination events at replicating chromosomes (117). Furthermore, the *sgs1 srs2* double mutant shows a severe growth which is alleviated upon blocking recombination by mutating *Rad51*, *Rad52*, *Rad55* or *Rad57* (89). A recent study from Liberi *et al.* shows that in *sgs1* mutants, recombination-dependent DNA intermediates accumulate at damaged forks, a phenomenon that requires the Rad51 protein, which is counteracted by the Srs2 protein and does not prevent fork movement (118). Sgs1, but not Srs2, promotes the resolution of these recombination intermediates. The integrity of these DNA structures at sister chromatid junctions is protected by the Rad53 checkpoint kinase. They also show that *top3* and *top3 sgs1* mutants accumulate the same structures as *sgs1* cells, arising from defective maturation of the recombination intermediates (118). The accumulation of HJs arising from fork reversal in *rad53* mutants has been shown by Sogo *et al.* (119).

Sgs1 in Checkpoint Activation and Replication Fork Maintenance

Frei and Gasser have observed that the deletion of *Sgs1* partially compromises the intra-S-phase checkpoint, which is largely mediated by the Rad53 kinase (91). Bjergbaek *et al.* later found that Sgs1 functions independently of both Top3 and Rad51 to stimulate the checkpoint kinase Rad53 upon replication fork stalling in response to HU treatment. This checkpoint activation is not dependent on the helicase activity of Sgs1 which correlates with the finding of direct interaction with Rad53. Furthermore, Sgs1 and Mrc1, which serves as mediator or adaptor for Rad53 activation, act in the same pathway for checkpoint activation. Moreover, they find that Top3 and Rad51 are required for DNA pol α and DNA pol ϵ stabilisation at stalled replication forks and that Sgs1 and Mrc1 act synergistically to stabilise DNA pol α and DNA pol ϵ at stalled forks (120; 121). The authors conclude that the checkpoint kinase activation requires Sgs1 as a noncatalytic Rad53-binding site, while the Top3/Sgs1 resolvase contributes to recovery of stalled replication forks (121). Fabre *et al.* have further shown that Sgs1 may be involved in the

repair of single-stranded gaps arising from replication (122).

The *SLX* genes and Mus81/Mms4

In a screen for mutations that show synthetic lethality in an *sgs1* background, Mullen *et al.* have found a group of genes that were named *SLX* (123; 124). A synthetic lethality was also found between the *slx* mutants and *top3*, indicative of a function in pathways parallel to that of Sgs1/Top3. *SLX6* was shown to be allelic to *Srs2*. Slx5 and Slx8 are putative RING/finger domain proteins that form a complex and are required for efficient sporulation. Slx1 and Slx4 also form a complex and Slx2 and Slx3 were demonstrated to be the two subunits of the Mus81-Mms4 heterodimeric complex that acts as a structure-specific nuclease (123; 124). Fabre *et al.* have later proposed that the single stranded DNA resulting from the stalling of replication forks can be processed by two competing mechanisms: Either recombination or nonrecombinational translesion synthesis. *Srs2* would channel recombination intermediates back into the translesion synthesis pathway, whereas Sgs1/Top3 and Mus81/Mms4 interact in recombination and/or replication to allow replication restart (122).

RAD16

Saffi *et al.* have shown that *Sgs1* is epistatic to the repair protein Rad16 with respect to cell survival after treatments with UVC, 4-NQO and H₂O₂ and that the defect in helicase activity of *Sgs1* is essential for most aspects of the *sgs1* mutation phenotype (90; 109). Rad16 has been shown to function in global genome repair of the nucleotide excision repair (125).

RMI1/NCE4

In a recent study, Chang *et al.* show that Rmi1 (RecQ-mediated genome instability, also known as NCE4) physically interacts with Sgs1 and Top3 (126). Cells lacking RMI1 activate the Rad53 checkpoint kinase, undergo a mitotic delay, and display increased relocalisation of the recombination repair protein Rad52, indicating the presence of spontaneous DNA damage. Consistent with a role for RMI1 in maintaining genome integrity, *rmi1* cells exhibit increased recombination frequency and increased frequency of gross

chromosomal rearrangements. In addition, *rmi1* strains fail to fully activate Rad53 upon exposure to DNA-damaging agents, suggesting that Rmi1 is also an important part of the Rad53-dependent DNA damage response (126).

Another recent study identified Rmi1/Nce4 as potential component of the Sgs1/Top3 pathway, based on the observation that strains lacking any one of these genes require Mus81 and Mms4 for viability. *sgs1* and *rmi1* mutants display the same spectrum of synthetic lethal interactions, including the requirements for Slx1, Slx4, Slx5, and Slx8. Like *sgs1 mus81*, the *rmi1 mus81* synthetic lethality is dependent on HR. On their own, mutations in Rmi1 result in phenotypes that mimic those of *sgs1* or *top3* strains including slow growth, hyperrecombination, DNA damage sensitivity and reduced sporulation. And like *top3* strains, most *rmi1* phenotypes are suppressed by mutations in Sgs1. They further show that Rmi1 forms a heteromeric complex with Sgs1-Top3 *in vitro* and *in vivo*. The Rmi1-Top3 complex is stable in the absence of the Sgs1 helicase, but the loss of either Rmi1 or Top3 in yeast compromises the interaction of the other with Sgs1. Further biochemical studies demonstrated that Rmi1 is a structure-specific DNA binding protein with a preference for cruciform structures suggesting that the DNA binding specificity of Rmi1 plays a role in targeting Sgs1-Top3 to appropriate substrates (127).

2.4 RECQ1

RECQ1, sometimes called RECQL or helicase Q1, is the smallest of the human RecQ helicases (see Figure 3) and was originally cloned independently by two groups (128; 129). The human *RECQ1* gene is located on chromosome 12p11-12 (128; 130). Zhang and Xi have described two variants resulting from alternative splicing (131). Interestingly, although a defect in RECQ1 has not been associated with a human disease yet, this chromosomal location has been found to coincide with cytogenetic alterations in testicular germ-cell tumours (132).

The first biochemical characterisation of RECQ1 was performed before its cDNA was cloned. Yanagisawa *et al.* purified DNA-dependent ATPases from HeLa cells and xeroderma pigmentosum (XP) cells to identify the cause of the disease and found that the ATPases purified from XP cells differed from those from HeLa cells (133). A 73 kDa ATPase, called ATPase Q1, was isolated and found to display 3'-5' helicase activity (134). The identified ATPase Q1 failed to complement XP-cell extracts from XP-C complementation group cells for DNA repair defects (129). The XPC helicase defective in these XP-C complementation group cells was identified in another work (135).

The purified RECQ1 was shown by Cui *et al.* to form dimers in the presence and absence of ssDNA, with an apparent molecular mass of 158 kDa (35; 61). Also, the kinetic studies on RECQ1-mediated unwinding suggested that the enzyme functions as a dimer (35).

RECQ1 is by itself a rather poor helicase, capable of displacing short partial duplexes. However, it displays an enhanced processivity upon interaction with human replication protein A (RPA) being able to unwind duplexes as long as 501 bp. This interaction is specific, as the *E. coli* single strand binding protein (SSB) did not stimulate RECQ1-mediated unwinding of long duplexes (61). Therefore, the enhancement of processivity is not achieved through merely coating the single stranded DNA, but rather through a specific protein-protein interaction facilitating the loading of the helicase onto the ssDNA/dsDNA interface. Furthermore, RECQ1 has recently been shown to unwind HJs, D-loops and to promote annealing of short oligonucleotides (44).

In a yeast two-hybrid screen, Seki *et al.* have identified RECQ1 to interact with Qip1 and Rch1, which are two of the three human importin α homologues involved in nuclear-cytoplasmic transport (136). This interaction was confirmed by the finding that Qip1 was

able to mediate nuclear transport of BSA when conjugated to the full RECQ1 nuclear localisation signal (NLS) (137).

2.5 BLM - The Bloom Syndrome Helicase

2.5.1 The Bloom Syndrome

The Bloom syndrome (BS) is a rare autosomal recessive disorder with a high predisposition to cancer development. BS was first observed in 1954 (138) and is caused by defects in the *BLM* gene, located on chromosome 15q26.1 (28). BS is characterised by a stunted growth, including disproportional growth, manifested in a small head and unusual facial and skull growths. Furthermore, male infertility and immunodeficiency, characterised by a decrease in IgA and IgM levels is observed in BS patients. Figure 7 shows a young BS patient who suffers from severe facial telangiectatic erythema. BS patients suffer from a 150-300 fold increase in the risk of developing malignancies of all types.

Figure 7: A BS patient. Adapted from Ref. (139). His sun sensitive telangiectatic erythema cover almost all his face.

2.5.2 BS Cellular Phenotype

The hallmark of cell lines derived from BS patients is the elevated rate of sister chromatid exchanges (SCEs) to about 10 fold. SCEs represent HR events between sister

chromatids during S phase or G₂ resulting in crossovers. In Figure 8, an example for elevated SCE levels in BS cells is shown. Similarly, ES cells as well as lymphocytes, primary or immortalised fibroblasts of *Blm* knockout mice (140; 141), murine *Blm* knock-out ES cells (142) and DT40 *BLM*^{-/-} chicken B-cells (143; 144) show an elevated rate of SCEs.

Figure 8: SCE analysis. Adapted from (145). To the left, chromosomes from a normal cell. To the right, chromosomes from a BS cell. Sister chromatids are distinguished through an assay based on differential labelling by BrdU.

It has been observed that BS cells as well as fibroblasts from *BLM*^{+/+} carriers show a tendency for the accumulation of micronuclei (146; 147) or to bud out micronuclei at an abnormally high rate (148). Furthermore, a comparatively high number of gaps, breaks and rearranged chromosomes can be observed in BS cells (149; 150; 143). Moreover, BS cells have been reported to display a significantly lower rate of chain elongation during DNA synthesis (151; 152). BS cells are sensitive to UV radiation (153; 144) and to the ribonucleotide reductase inhibitor hydroxyurea (HU) (154; 155).

2.5.3 BLM - The Protein

The BS protein (BLM) is 1417 amino acids long, was cloned (18) and purified and characterised (62), where it was found that the protein displays ATP-dependent 3'-5' helicase activity. Furthermore, BLM has been found through gel-exclusion chromatography and electron microscopy to form ring-oligomeric structures with hexamers being the most prominent forms (156). BLM is able to unwind a wide variety of structures as depicted in Table 2 with a preference for quadruplex DNA and HJs (48; 157). The most important biochemical finding on BLM to date is, that in conjunction with *TOPOIII α* , it is able to

resolve DHJs via a strand passage mechanism that prevents exchanges between flanking sequences (4). This reaction is called DHJ dissolution and is illustrated in Figure 9. DHJs have been described to be intermediates in meiotic recombination (158) and are predicted to form in mitotic cells during repair of DSBs by HR. As BS cells are not hypersensitive to ionizing radiation, BLM presumably does not carry an essential role in DSB repair (159). It is thought that the non-meiotic DHJs arise from HR-dependent repair of daughter strand gaps formed during replication (159; 4). The DHJ dissolution reaction explains many of the phenotypes of BS cells, but most importantly, the cause of the elevated rate of SCEs is revealed. In addition, BLM has also been reported to mediate strand exchange *in vitro* by Machwe *et al.* (160).

The expression of BLM cells is cell-cycle dependent; The protein level peaks in S, persists in G₂/M and is degraded in G₁, consistent with its role in S and G₂. BLM is a phosphoprotein and is phosphorylated during mitosis (154; 161) and in response to γ -radiation (162; 163; 155). The kinase responsible for this phosphorylation seems to be ATM (Chapter 2.5.4). Also, BLM can be sumoylated (Chapter 2.5.4). Furthermore, BLM is a downstream target of the ATR-Chk1 pathway.

Figure 9: The DHJ dissolution reaction. Adapted from (4). BLM and TOPOIII α together dissolve the structure depicted to the right into its components. In the experimental setup, one of the component oligonucleotides is labelled radioactively and will be detected as single species upon visualisation of radioactivity.

2.5.4 Interaction Partners of BLM

Many of the interaction partners of BLM listed below indicate that BLM is recruited to and activated at sites of recombination, probably to ensure the correct resolution of aberrant structures without cross-overs.

ATM, ATR and DNA Damage Response

In cells from ataxia telangiectasia (AT) patients - they lack the ataxia telangiectasia mutated protein (ATM) - the mitotic and the γ -radiation-induced phosphorylation of BLM are absent (153; 164; 163), but the ATR-dependent phosphorylation of BLM in response

to HU or UVC treatment is not altered (153; 164). ATM appears to be activated primarily by ionizing radiation or radiomimetic drugs that generate double-strand breaks (165). BLM has been reported to interact with ATM by Beamish *et al.* (154). Also, BLM interacts with ATR and evidences have lead to the suggestion that BLM is also a downstream target of ATR (164). It was shown that BLM forms foci with γ H2AX at broken replication forks and that these foci recruit BRCA1 and NBS1 (166). Later, it was found that BLM localises into nuclear foci with phosphorylated γ H2Ax and RAD51 and proposed that this is a response to restore productive DNA replication following S-phase arrest (155). BLM is very likely to be required at these sites to resolve the arising recombination intermediates.

Sengupta *et al.* have observed that BLM co-localised with the DNA damage response proteins 53BP1 and H2AX. Furthermore, BLM facilitated the physical interaction between p53 and 53BP1, but 53BP1 was required for the efficient accumulation of BLM and p53 at sites of stalled replication. The formation of BLM/53BP1-foci was independent of γ -H2AX. The Chk1 active kinase was essential for the focal co-localisation of BLM and 53BP1 and for the consequent stabilisation of BLM. The authors propose that BLM functions in repair processes upon receipt of the signals mediated by 53BP1 and from ATR/Chk1 from replicational stress (167).

The BASC complex

Wang *et al.* have identified a high-order complex consisting of many DNA repair factors, BLM amongst them, and called it BASC, standing for **BRCA1-associated genome surveillance complex** (168). The complex includes tumour suppressors and DNA damage repair proteins: BRCA1, BLM, MSH2, MSH6, MLH1, ATM, RAD50-MRE11-Nbs1 (MRN complex) and RFC. Especially, it was found that BRCA1, BLM and the MRN complex form large nuclear foci containing PCNA upon treatment with DNA-synthesis inhibiting agents.

The BRAFT Complex

Upon immunoprecipitation of BLM from HeLa cells, Meetei *et al.* identified by mass spectrometric methods a complex that includes BLM, TOPOIII α , RPA and the five core Fanconi anemia (FA) proteins FANCA, FANCC, FANCE, FANCF and FANCG and called this

complex BRAFT. BLM is responsible for the unwinding activity in this complex (169). Pichierri *et al.* have shown that BLM and FANCD2 colocalise and co-immunoprecipitate upon treatment with DNA crosslinkers or agents inducing replication fork arrest, again indicating a functional interaction (170). The features of the BS are very different to those of the FA, but some aspects of genomic instability in these diseases are similar. For a review on the Fanconi anemia proteins, see Ref. (171).

CAF-1

Jiao *et al.* found that BLM interacts with hp150, the largest subunit of the chromatin assembly factor 1 (CAF-1) *in vivo* and *in vitro*. The two proteins were found to co-localise at nuclear foci at sites of DNA synthesis. The fraction of co-localising foci was increased upon DNA damage or replication inhibition. BLM could inhibit CAF-1-mediated chromatin assembly *in vitro*. The activity of CAF-1 was not affected in BLM deficient cells, CAF-1 could not be mobilized in the nucleus upon hydroxyurea treatment. The authors suggested that BLM and CAF-1 function in a coordinated way to promote survival in response to DNA damage and/or replication blockage (172).

PML

The promyelocytic leukemia protein (PML), is a tumour suppressor and has been found to localise into specific structures called PML bodies, where many proteins involved in DNA metabolism localise to (173; 174; 175). BLM trafficks into PML bodies in a manner dependent on SUMO modification (176).

MutS α - the MSH2/MSH6 heterodimer

Marsischky *et al.* observed, that the *S. cerevisiae* MSH2/MSH6 heterodimer (MutS α) interacts with HJs and may help resolving them (177), providing a first evidence for a possible role of DNA mismatch repair (MMR) proteins in HR. Later, it was found that BLM associated with the human MutS α through direct interaction with hMSH6 *in vivo*. BLM and MSH6 co-localise at nuclear foci upon exposure to ionizing radiation. The authors did not observe an effect of MutS α on unwinding activity of BLM (178). Yang *et al.* have further investigated this interaction and found that the purified MutS α could

stimulate the BLM-mediated HJ branch migration *in vitro* and that this interaction could be regulated by p53. Furthermore, hMSH6 co-localised with BLM and p53 phosphorylated at Ser-15 in hydroxyurea-induced RAD51 foci. Moreover, they showed hMSH2 and hMSH6 to coimmunoprecipitate with BLM, p53 and RAD51. Moreover, they observed that the number of RAD51 foci and the amount of the BLM-p53-RAD51 complex was increased in cells deficient in hMSH2 or hMSH6 (179). The authors deduct from these data that MutS α forms a complex with BLM-p53-RAD51 in response to the damage of DNA replication forks to promote DSB repair. This assumption may not quite explain why the mismatch-sensor complex MutS α would be required at these sites. An intriguing model would be that the MutS α /BLM interaction serves for preventing homeologous recombination (HR between not perfectly homologous sequences). For a review on MMR, see Ref. (180).

MLH1

MLH1, one of the eukaryotic homologues of the MutL from *E. coli*, is part of the heterodimeric complex MutL α consisting of MLH1 and PMS2 that is recruited to sites of DNA-mismatch-specific bound MutS α or MutS β complexes during MMR (181). BLM and MLH1 have been found to interact *in vivo* and *in vitro*. Furthermore, BLM and MLH1 co-localise in untreated as well as in aphidicoline-treated cells (182). As BLM deficiency does not result in a MMR defect, BLM is very unlikely to play a role in this reaction (182; 183).

p53

Wang *et al.* found that BLM and p53 are likely to regulate apoptosis since they observed that the ectopic expression of p53 induces apoptosis in normal cells but not in BS cells. As BS cells show normal Fas-induced apoptosis, this effect seems specific for the p53 apoptotic pathway (184). However, Davalos and Campisi claim that p53-induced apoptosis also occurs in BS cells (166)

In vivo, BLM and p53 phosphorylated on Ser-15 partially co-localise (185). BLM and p53 also co-immunoprecipitate from cell extracts (184; 185) and have been shown to physically interact *in vitro* (186). p53 is able to inhibit the unwinding activity of BLM on HJs, but not on standard oligonucleotide substrates. p53 may therefore be involved

in the regulation of HR through modulating the interaction of BLM with recombination intermediates (185). Furthermore, Garkavtsev *et al.* have observed that the ectopic expression of BLM causes an anti-proliferative effect in p53 wild-type cells, but not in p53-deficient cells. Moreover, the p53-mediated transactivation is attenuated in primary BS fibroblasts (186).

Rad51

The eukaryotic Rad51 protein and its paralogs are orthologues of the bacterial RecA protein which is involved in HR and DNA repair. Rad51 forms a nucleoprotein filament on ssDNA to mediate strand exchange. BLM and the human Rad51 have been shown to interact both *in vivo* and *in vitro*. In some untreated cells, BLM and Rad51 co-localise in late S-phase, and this is enhanced upon γ -radiation and aphidicolin treatment (187; 162). Rad51 and BLM have also been observed to co-localise in early meiotic cells at sites of interhomologue-DNA transactions (188).

RPA

The replication protein A (RPA) is a human single-stranded DNA binding protein that exists as a heterotrimer formed by subunits of 14, 32 and 70 kDa. BLM interacts physically with RPA through the p70 subunit (54; 183) and co-localises with the p34 and p70 subunits of RPA at nuclear foci in normal fibroblasts (189). *In vitro*, BLM is able to unwind partial duplexes of up to 100 bp, whereas, in a reaction together with RPA, partial duplexes as long as 259 bp can be unwound. This enhancement of helicase activity is not achieved through stimulation of ATPase activity (54; 47).

TOPOIII α

The type I topoisomerase TOPOIII α co-localise with BLM at nuclear foci in growing, normal fibroblasts as well as in transformed human fibroblasts (190) and interacts directly with BLM in the dissolution of DHJs in a non-crossover manner (Chapter 2.5.3) (4).

TRF2

In telomerase-negative cells that maintain their telomeres by a different mechanism called alternative lengthening of telomeres (ALT), BLM colocalises with the telomere repeat binding factor 2 (TRF2) in atypical, telomere-associated PML bodies. Also, TRF2 and BLM could be co-immunoprecipitated, suggesting an *in vivo* role of this association (191). TRF2 also interacts with BLM physically and stimulates its helicase activity on forked duplexes with or without two telomeric repeats. TRF2 is unable to bind these structures, as it requires more telomeric repeats (47).

WRN

WRN and BLM have been reported to interact directly *in vivo* and *in vitro* and that this interaction has a functional consequence in regulating the exonuclease activity of WRN (63). This interaction is certainly not the only way for the two proteins to function, as only a small portion of WRN could be co-immunoprecipitated with BLM (63), and BS is quite different from the Werner syndrome.

2.6 WRN - The Werner Syndrome Helicase

2.6.1 The Werner Syndrome

Like BS, the Werner syndrome (WS) is a rare autosomal disorder associated with high predisposition to cancer. It has been described for the first time in the PhD thesis of Otto Werner in 1904 (29). This syndrome arises from defects in the *WRN* gene. Only by the work of Thannhauser (192) this disease was clearly distinguished from the Rothmund-Thompson syndrome (Chapter 2.7). WS starts to be apparent in adolescence where the usual growth spurt does not take place, leading to a short stature. As also seen with BS patients, the facial features are thin and appear bird-like as a result of the stunted growth. The skin is affected by unusual pigmentation patterns, and hyperkeratoses appear at bony areas of the skin, such as for example at the limbs, and often acquires ulcers at such places. The earliest and clearest signs of WS is the early onset of various features of ageing such as hair greying and thinning, osteoporosis and soft tissue calcification. Furthermore, diabetes mellitus at an unusual early stage can evolve as well as arteriosclerosis, hypermelanosis and cerebral cortical atrophy. WS is not only characterised by premature ageing but also a higher incident of malignancies is observed (193). These malignancies, unlike the ones observed in BS, are mostly of epithelial and mesenchymal origin. Therefore, WS patients have a predisposition to develop soft tissue sarcomas, osteosarcomas, acral lentigenous melanomas, meningiomas and thyroid carcinomas (194). In contrast to the ageing symptoms, it has been observed that WS patients have a lower incidence of Alzheimer-like neuropathologies (195). Figure 10 shows a typical WS patient.

Figure 10: A Japanese-American WS patient as a teenager (left) and at the age of 48 (right). She was patient number 1 in the study of Epstein *et al.* and deceased at the age of 57, a high age for WS patients. Adapted from Ref. (193).

2.6.2 WS Cellular Phenotype

The *WRN* gene has been positionally cloned and is located in the p11-p12 region on chromosome 8, spanning 180 kb (30; 196). In culture, WS cells have been shown to undergo replicative senescence at a faster rate than normal cells which is considered to be the hallmark of WS cells with an average lifespan of only 27% of normal cells (197). A recent study shows that the WS cells are defective in lagging strand synthesis of telomeres and therefore will suffer from a single telomere loss and further argues for WRN being involved in replication, presumably by disrupting quadruplex DNA that may form on the G-rich lagging strand template (198). Furthermore, the growth defects of WS cells are retained after transformation (199). The expression of telomerase hTERT reverses the poor growth and the entry into premature senescence phenotypes of WS cells but seems not quite sufficient to immortalise the cells (200; 199). WS cells have been reported to be sensitive to 4-nitroquinoline 1-oxide (4NQO) (144; 201; 202). This effect can be reverted by expressing hTERT in SV40-transformed WS cells (203). WS cells have further been reported to be sensitive to DNA cross-linking drugs such as mitomycin C and cisplatin (199; 202; 204). Furthermore, WRN-deficient human and murine cells are sensitive to camptothecin, an inhibitor of Topoisomerase I (205; 206). Sensitivity to γ -radiation and radiomimetic drugs is debated, since several groups have shown different responses of WS cells to these treatments (144; 199; 201; 207).

The hallmark of WS cells at the chromosomal level is the elevated rate of extensive

somatic deletions and translocations which can vary in different clones (208; 209). Furthermore, WS cells display a higher number of RAD51 foci than normal cells, which probably indicates the persistence of unprocessed recombination intermediates (210). Unlike in BS cells, no increase in SCE-frequency is seen in WS cells (144; 211; 212).

WRN seems not to be involved in homologous recombination. Instead, its strong interaction with Ku rather suggests a role in non-homologous end-joining, in a manner that Ku regulates the WRN exonuclease in resection of DNA at non-homologous ends (Chapter 2.6.4). This action is likely not to be the sole on DNA ends, as WS cells do not show an obvious DNA double strand break (DSB) repair defect.

2.6.3 WRN - The Protein

The WRN protein is 1432 amino acids long and contains two functional domains: the central helicase domain and the N-terminal exonuclease domain. Furthermore, it carries an unusual direct repeat of 27 amino acids located between the exonuclease and the helicase domains (Figure 3).

WRN displays an ATP-dependent 3'-5' helicase activity. As most other RecQ helicases, it is able to unwind D-loops, G-quadruplex DNA and to migrate Holliday junctions (Table 2). The N-terminal nuclease domain displays 3'-5' polarity and shows low processivity (213). Orren *et al.* have observed that WRN *in vitro* will as helicase unwind the duplex of the invading strand in a D-loop structure and as 3'-5' exonuclease digest the invading strand (53). WRN has also been reported to mediate strand exchange *in vitro* (160), but the activity observed may be debated as the reaction conditions were far from physiological.

The cellular WRN protein levels are elevated during cytologic transformation of B-cells and fibroblasts and decreased when fibroblasts in culture reach confluency, indicative of a role of in proliferating cells (214). The expression of WRN is cell-cycle regulated, with the concentration peaking in the G₂/M phases (215). WRN is present in the nucleolus and migrates from nucleoli to nuclear foci upon treatment with HU, aphidicolin, 4NQO or camptothecin (216; 217; 218; 219; 220).

2.6.4 Interaction Partners of WRN

DNA-PK complex

The DNA-PK complex consists of DNA-PK_{cs} and the Ku70/Ku80 heterodimer. It has been shown that WRN interacts with both the Ku heterodimer (221; 222; 223; 224; 225; 226) and DNA-PK_{cs} (207). WRN is phosphorylated *in vivo* and *in vitro* by DNA-PK (207). The Ku70/Ku80 heterodimer strongly stimulates the exonuclease activity of WRN (223; 224; 207; 227), which is alleviated by poly(ADP-ribosyl)ation of Ku70/Ku80 (228). Not only does the Ku70/Ku80 stimulate the exonuclease activity of WRN, but it also extends the substrate specificity, so that WRN is able to degrade 3' protruding or blunt ends (223). Moreover, the inhibition of WRN exonuclease activity by 8-oxoG and 8-oxoA is alleviated by Ku70/Ku80 (229; 222).

DNA polymerase β

DNA polymerase β (pol β) is a key polymerase in both short and long-patch base excision repair (BER) (for a review on BER, see Ref. (230)). WRN has been shown to physically interact with pol β and to stimulate strand-displacement DNA synthesis of pol β (231). Furthermore a truncated variant consisting mainly of the helicase domain was sufficient to stimulate pol β (231).

DNA polymerase δ

Kamath-Loeb *et al.* could show that WRN interacts with DNA polymerase δ (pol δ), a polymerase required for DNA replication and repair. WRN increases the nucleotide incorporation by pol δ in the absence of PCNA but not that of the polymerases α or ϵ (232). The same group further showed that this interaction specifically facilitates the pol δ -mediated DNA replication of templates forming secondary structures like quadruplex DNA and/or DNA repair (233). This hypothesis correlates with the observed S-phase defects in WS cells, namely defective lagging strand synthesis at telomeres observed after WRN depletion in HeLa cells (198).

EXO1

The human exonuclease 1 (EXO1) is a 5'-3' exonuclease and a 5'-flap-specific endonuclease and it has been proposed to function in DNA recombination and MMR. The exonucleolytic and the endonucleolytic activities have both been shown to be stimulated by WRN (234). Moreover, EXO1 and WRN interact physically *in vivo* and *in vitro* (234).

FEN1

The flap-endonuclease 1 (FEN1) is a protein that acts in DNA replication to remove the 5' overhang that arises at Okazaki fragments (235) and is also responsible for the removal of 5' overhangs arising in strand displacement synthesis during base excision repair (236). Brosh *et al.* have shown that WRN interacts with FEN1 and greatly stimulates the FEN1 nuclease activity (46). Sharma *et al.* further show by FRET (fluorescence resonance energy transfer) that WRN and FEN1 form a complex *in vivo* that co-localises with foci associated with arrested replication forks. WRN stimulates FEN1 cleavage of branch-migrating double-flap structures (237). Moreover, they show that *in vitro*, WRN unwinds Holliday junctions and stimulates FEN1 to cleave the unwound product (237).

MYC

MYC is an oncoprotein and acts as a transcription factor coordinating cell growth and division. When overproduced, it has been found to sensitize cells to agents stimulating apoptosis (238). Grandori *et al.* reported that MYC directly stimulates transcription of WRN and that the overexpression of MYC in WS fibroblasts or after WRN depletion from control fibroblasts led to rapid cellular senescence that could not be suppressed by hTERT expression. They proposed that WRN up-regulation by MYC may promote MYC-driven tumorigenesis by preventing cellular senescence (239). A discussion of the link between MYC and WRN in tumourigenesis is laid out by the same group in Ref. (240).

p53

The tumour suppressor protein p53 interacts physically with WRN both *in vitro* and *in vivo* (241; 185; 217). Yang *et al.* have further shown that this interaction modulates the

activities of both partners. p53 inhibits WRN-mediated unwinding of Holliday junctions, but only if it is not phosphorylated at Ser-378 and is also able to inhibit the exonuclease activity of WRN (217). WRN enhances the transcription of p53-responsive promoters in transfection assays. Ectopic expression of WRN also leads to higher p21 protein levels (241).

RNA polymerase II transcription

Balajee *et al.* found that in permeabilised WS cells the efficiency of transcription of a plasmid template containing the RNA polymerase II- dependent adenovirus major late promoter is reduced to 40-60% compared to normal cells. This reduction in transcription efficiency is reverted by the addition of the WRN protein. This effect seems to be mediated by the direct repeat of 27 amino acids ahead of the helicase motifs, as the authors show that a WRN mutant lacking the direct repeat fails to stimulate the low RNA pol II transcription rate of WS cells (242).

RPA

WRN alone can only unwind partial duplexes up to 40 bp, but in the presence of RPA it is able to unwind partial duplexes as long as 849 bp without an increase in ATPase activity (243). RPA does not effect the exonuclease activity of WRN (222). The physical interaction between WRN and RPA has been shown *in vitro* (243).

TRF2

In telomerase-negative cells that maintain their telomeres through the ALT pathway, WRN co-localises with TRF1, TRF2, PML, RAD52 and NBS1 in nuclear structures called ALT-specific, atypical PML bodies. In HeLa cells, where the telomerase is present, WRN localises to the nucleolus (86). As observed with BLM, TRF2 interacts with WRN physically and stimulates the helicase activity of WRN on forked duplexes with or without two telomeric repeats (47). The exonuclease activity of WRN is not affected by this interaction (47). Opresko *et. al* further showed that WRN associates with telomeres when dissociation of telomeric D-loops is likely during replication and recombination. They observed that most TRF1/PCNA co-localising nuclear foci contain WRN in S

phase ALT cells but not in telomerase-proficient HeLa cells. TRF1 and TRF2 limits the WRN-mediated disruption of D-loops (244). WRN is thus very likely to be involved in ALT.

WHIP

The Werner helicase interacting protein (WHIP) is a protein of 660 amino acids with homology to the replication factor C (RFC) family proteins. WHIP interacts with WRN, but not with BLM or RECQ1. The function of this protein is unknown to date (245).

2.7 RECQ4/RTS- The Rothmund-Thomson Syndrome Protein

2.7.1 The Rothmund-Thomson Syndrome

The Rothmund-Thomson syndrome (RTS) is a rare autosomal recessive disorder with roughly 200 reported patients worldwide. RTS has first been described in 1868 by Rothmund, a German ophthalmologist. Patients from a German family suffered from unusual skin degeneration and cataracts, a condition where the lens of the eye gradually turns opaque and results in a blurred view (31). 68 years later, Thomson, a British dermatologist described a syndrome with skin abnormalities and skeletal malformations and called it Poikiloderma congenitale (32). In 1957, Taylor recognised that the two syndromes are manifestations of the same disease and called it therefore RTS (33).

Through a number of patient studies it is known that RTS confers a high incidence of malignancies, mainly osteosarcomas (246; 247; 248; 249; 250; 251; 252; 253). Patients suffer from retarded postnatal growth and skin abnormalities that manifest as poikiloderma and sun-sensitive rash. Most patients also have sparse hair and eyebrows. Furthermore, diverse skeletal abnormalities arise, such as a decrease in bone density (osteopenia), pathological fractures, dislocations and metaphysis. In many cases, the so-called "radial ray defect" is immediately apparent, which manifests as appendages of the thumb or small, missing or bifid thumbs. Often, cataracts appear, whereas mental or gonadal problems are varying from patient to patient. RTS has been found in some cases to be associated with a defect in the *RECQ4* gene (254). Wang *et al.* have later classified RTS into RTS type I, which represents RTS without a predisposition to osteosarcomas and with an intact *RECQ4*, and into RTS II that is characterised by a defective *RECQ4* and a high predisposition to osteosarcomas (250). Figure 11 shows a female RTS patient.

Figure 11: A female RTS patient. Adapted from Ref. (255). The picture to the left shows the usual strong manifestation of poikiloderma, also the hair is sparse and the eyebrows are missing. The patient's arm suffers from eczematous lesions and bulla formation. The skeletal development of the hand appears normal. The patient further suffered from severe infections of the respiratory tract.

Another disease associated with a defective *RECQ4* gene has been recently identified: the RAPADILINO syndrome, characterised by **radial** hypoplasia, **patella** hypoplasia and cleft or arched palate, **diarrhea** and dislocated joints, **little** size and limb malformation, **nose** slender and normal intelligence. Unlike the RTS, RAPADILINO does not display the same high predisposition for malignancies (256).

Interestingly, the distinction between the two syndromes is also seen at the genetic level, as RTS patients with a defective *RECQ4* gene are mainly compound heterozygotes of nonsense or frameshift mutations, resulting in a *RECQ4* polypeptide lacking a large part of the helicase domains (248; 254; 257), whereas most of the RAPADILINO patients are compound heterozygotes in which at least one of two defective *RECQ4* alleles contains a deletion that causes, upon pre-mRNA splicing, the skipping of exon 7 without frameshift leading to a polypeptide with an intact putative helicase domain of *RECQ4* (256).

2.7.2 RTS Cellular Phenotype

RTS cells have been reported to be genetically unstable, displaying a high frequency of chromosomal abnormalities such as translocations and trisomies (258; 259; 260; 261; 262). Cultured cells from RTS patients show normal sensitivity to mitomycin C, bleomycin, vincristine, methotrexate (248), cisplatin and adriamycin (263). The rate of sister chromatid exchanges is also normal in RTS cells (248). However, RTS cells show an increased sensitivity to ionizing radiation (263; 264; 265), probably due to a reduced level of DNA repair synthesis and an abnormally low rate of the removal of radiation-induced DNA lesions (264). The low DNA repair capacity is also an explanation for the UV sensitivity and reduced unscheduled DNA synthesis after UVC exposure observed in RTS cells (266).

2.7.3 RTS/RECQ4 - The Protein

The *RECQ4* gene has been cloned by Kitao *et al.* before it was known to be associated with RTS (215). It lies on the p-arm of chromosome 8 at 24.3 spanning 6.5 kb and includes 21 exons (267). The RECQ4 protein of 1208 amino acids harbours the helicase domains, but seems to lack the Zn²⁺-binding domain as well as the WH and HRDC domains.

The RECQ4 protein is present in all phases of the cell cycle, but apparently peaks in S and G₂, again indicating replicative or postreplicative roles of RECQ4(267). Yin *et al.* have recently shown that the RECQ4 protein is present in the nucleus as well as in the cytoplasm of HeLa cells and preliminarily characterised biochemical activities of the immunoprecipitated protein. They could observe an ATPase activity with ssDNA or dsDNA as co-effectors but the protein failed to displace synthetic DNA duplexes (268) or to melt a triple helix. The authors conclude that RECQ4 may be similar to the SWI/SNF chromatin-remodelling factors, members of the SF2 family that show ATPase activity but not helicase activity *in vitro*. The absence of the Zn²⁺ binding domain remains enigmatic even in this context.

Using *Xenopus laevis* as a model system, Sangrithi *et al.* have found that xRTS, the *X. laevis* homologue of RECQ4, is essential for DNA replication in egg extracts (269). They observed that xRTS accumulates on chromatin during replication initiation after establishment of the prereplication-complex but before the recruitment of replicative

polymerases. Furthermore, xRTS depletion suppressed the loading of RPA that marks unwound origins before polymerase recruitment. The authors conclude that xRTS functions after the formation of the prereplication-complex to promote loading of replication factors, an activity previously unrecongised but apparently necessary for initiation of replication (269). This role in replication initiation may explain the cause of chromosomal abberations of type II RTS cells.

2.7.4 Interaction Partners of RECQ4

UBR1 and UBR2

UBR1 and UBR2 are very similar proteins that are the components of ubiquitin (Ub) ligases (E3) of the N-end rule pathway, one pathway of the Ub-proteasome system. Yin *et al.* could isolate a protein complex consisting of RECQ4 UBR1 and UBR2 mainly from the cytoplasm and observed that this complex displayed DNA-stimulated ATPase activity, but failed to display helicase or translocase activities. Furthermore, they showed that RECQ4 is not ubiquitylated *in vivo* and is a long-lived protein in HeLa cells (268).

p53

Recently, p53 has been shown to repress the transcription of *RECQ4* in G₁-arrested cells, both in the absence and presence of DNA damage. Tumour-derived mutant forms of p53 were not able to repress the transcription of *RECQ4*. Arresting the cells by the topoisomerase-inhibitors etoposide (arrest in G₂) or camptothecin (arrest in S) led to further accumulation of p53 and concomitant decrease in the amount of RECQ4. Histone deacetylase 1 (HDAC1) was shown to be normally recruited to the *RECQ4* and *p21* promoter. Trichostatin A (TSA), an inhibitor of all histone deacetylases (HDACs) inhibited the p53-mediated repression of the *RECQ4* promoter, probably due to a conformational change of HDAC1 as it was observed that it was no longer bound to the promoter upon camptothecin treatment. The authors of this work proposed that the p53-mediated repression of *RECQ4* transcription during DNA damage results from the modulation of the *RECQ4* promoter occupancy by transcription activators and repressors (270).

2.8 RECQ5

2.8.1 Discovery of RECQ5

RECQ5 is the fifth human homologue of the *E. coli* RecQ and has not been associated with any syndrome yet. Kitao *et al.* identified a small isoform of RECQ5, which was later denoted RECQ5 α (215). In this work, they cloned a cDNA with homology of 48% to the helicase domain of RecQ. The cloned gene encoded for a 410 amino acids long polypeptide. Because of the relatively small size compared to the other human RecQ homologues, the authors classified this RECQ5 variant as a member of a small group. FISH analysis revealed the corresponding gene to be located on the q arm of chromosome 17 at the 25 region. The gene was found to be expressed ubiquitously with the highest levels in testis and ovary (215).

A year later, Sekelsky *et al.* reported their work on cloning the *Drosophila melanogaster* RecQ5 (DmRecQ5) (271). The discovery of the DmRecQ5 was coincidental, as they found it while cloning an unrelated cell-cycle checkpoint gene by screening a *Drosophila* embryo cDNA library. They found two RECQ5 isoforms of 54 kDa and 121 kDa generated by alternative splicing. The shorter one consists of the conserved helicase domains and is similar to the previously reported human RECQ5 protein and the longer one, in addition to the helicase region, contains a long C-terminal part bearing many charged residues without homology to any other RecQ helicase. Furthermore, they showed that the long isoform of DmRecQ5 localises to the nucleus. The authors also extended their study to the human RECQ5 and observed that the cDNA from Kitao *et al.* was incomplete at the 5' end and used this clone to screen a brain cDNA library. They found a cDNA coding for a protein of 49 kDa, which would be a bit longer than the 46 kDa protein identified by Kitao *et al.* As both cDNAs contained a polyadenylation signal at the 3' end, it was assured that both constructs were from genuine coding mRNA. Although the two cDNAs were almost identical, the one identified by Sekelsky *et al.* was slightly longer than the other at the 3' end. It was concluded that the resulting protein would be generated from a different alternative splicing to yield a protein containing additional 25 amino acids. The protein variant Sekelsky *et al.* had discovered in this work was actually later denoted RECQ5 γ . Furthermore, they speculated on the existence of two additional variants, of which one was later cloned and named RECQ5 β (see below) (271). Another attempt to clone RECQ5 DNA from human testis mRNA revealed

three different splice variants named α , β and γ . The structure of these transcripts are shown in Figure 12 (272). Furthermore, it has been shown that RECQ5 β localises to the nucleus, whereas the short isoforms RECQ5 α and RECQ5 γ are only present in the cytoplasm. The authors also report an interaction of RECQ5 β with the topoisomerases III α and III β (272).

Figure 12: Structure of the *RECQ5* gene and the encoded RECQ5 proteins. Adapted from Ref. (272). (a) Genomic structure of the *RECQ5* gene and the exon organisations of three RECQ5 mRNA isomers, RECQ5 α , RECQ5 β and RECQ5 γ . (b) Schematic representation of the RECQ5 isomers, the sizes are given on the right. The darkened areas indicate the locations of the helicase domains shared by the RecQ helicase family. The hatched areas indicate the extended homologous region to *E. coli* RecQ helicase and correspond to the Zn²⁺-binding domain. RECQ5 γ contains RECQ5 α plus an additional 25 unconserved amino acids resulting in 435 amino acids.

2.8.2 *Drosophila melanogaster* RECQ5

Ozsoy *et al.* have performed the first biochemical characterisation of DmRecQ5b, the small *Drosophila melanogaster* RECQ5 isoform of 54 kDa. They subjected it to classical helicase assays and observed that the protein displayed 3'-5' ATP (dATP)- dependent helicase activity on partial duplexes as long as 93 bp. Furthermore, they observed that the protein shows higher helicase activity with dATP than with ATP, with turnover rates of 1380 min⁻¹ and 900 min⁻¹, respectively (273). In a later work, the same group

extended the biochemical characterisation of DmRecQ5b and found that it is a structure-specific helicase like the other RecQ helicases. The protein unwound 3'-flaps, three-way junctions and synthetic forks more efficient than 5'-flaps and 12 nt-bubble substrates. DmRecQ5 also unwound synthetic Holliday junctions. Moreover, they observed that the protein shows a preference for unwinding the "lagging-strand arm" in a synthetic structure resembling a replication fork pointing to a role of DmRecQ5 in the recovery of stalled replication forks (274).

Kawasaki *et al.* expressed the large DmRecQ5c isoform of 121 kDa in the baculovirus system and subjected it to various *in vitro* assays. In gel filtration experiments, they observed that the proteins forms oligomers. Furthermore, they observed that DmRecQ5 hydrolyses GTP more efficiently than ATP in the presence of ssDNA. However, the helicase activity of DmRecQ5c was promoted by ATP and not by GTP. Nevertheless, GTP had a stimulatory effect on ATP-driven DNA unwinding (275).

To explore the cellular role of *Drosophila melanogaster* RECQ5, Nakayama *et al.* expressed the DmRECQ5 in an *sgs1* yeast mutant. DmRECQ5 was able to complement the *sgs1* phenotypes of the synthetic growth defect with *srs2*, the hypersensitivity to hydroxyurea and to MMS and also the elevated rate of sister chromatid exchanges (SCEs), but only poorly complemented the suppression of slow growth in *top3*. They further show that the helicase domain and helicase activity of DmRecQ5 was required to complement both the *sgs1 srs2* and the *sgs1 top3* phenotypes. The C-terminus of DmRECQ5 was dispensable for complementing the *sgs1 srs2* phenotype, but was required for complementation of *sgs1 top3*. These data further imply that the RecQ functions are highly conserved. It is still unclear, why the elevated rate of SCEs was complemented, but the slow growth of the *top3* could not be reverted (276).

2.8.3 RECQ5 and SCEs

Wang *et al.* used the chicken B-cell line DT40 to study the consequences of knocking-out the chicken orthologues of alone or in different combinations (277). The DT40 cells are a popular system to study gene knock-outs as the high rate of homologous recombination observed in these cells allows to knock out genes by gene targeting. In this work, the authors generated the following mutants: *RECQ1*^{-/-}, *RECQ5*^{-/-}, *BLM*^{-/-}, *RECQ1*^{-/-}/*RECQ5*^{-/-}, *RECQ1*^{-/-}/*BLM*^{-/-} and *RECQ5*^{-/-}/*BLM*^{-/-} and tested them for the sen-

sitivities to MMC, MMS and UV-light treatments, and also monitored the rate of spontaneous or MMC-induced SCEs. They found that both the *RECQ1*^{-/-} *BLM*^{-/-} and the *RECQ5*^{-/-} *BLM*^{-/-} mutants grew slower than the *BLM*^{-/-} cells due to the increase in the number of dead cells, suggesting a role for *RECQ5* and *RECQ1* in cell viability in the absence of BLM. Moreover, the *RECQ5*^{-/-} *BLM*^{-/-} mutant showed an elevated rate of SCEs compared to *BLM*^{-/-} cells, whereas this effect was not seen with the *RECQ1*^{-/-} *BLM*^{-/-} mutant. The authors failed to observe a change in sensitivity to UV upon inactivating *RECQ5* in a *BLM*^{-/-} background. Finally, the *RECQ1*^{-/-} and the *RECQ5*^{-/-} single and double mutants did not show a significant difference from the wild-type cells in growth, sensitivity to DNA-damaging agents and frequency of SCE (277). This suggests that the absence of BLM creates substrates for *RECQ5* that do not appear in normal cells. This work shows a first implication of *RECQ5* in suppressing SCEs, but the chicken B-cell line DT40 may not be an ideal model system for the elucidation of the role of the human *RECQ5* protein as the chicken orthologue is only 649 amino acids long.

Recently, Hu *et al.* have taken the issue of *RECQ5* being implicated in suppressing SCEs further into murine ES cells (142). They observed that in *RECQ5*^{+/-} murine ES cells, that grew normally, the level of SCEs is the same as in wild-type cells, whereas in real *RECQ5*^{-/-} cells, which also grew normally, the rate of SCEs is elevated approximately three-fold compared to wild-type or heterozygous cells. A further confirmation of this phenotype was obtained with mouse embryonic fibroblasts (MEFS) derived from the ES cells. This elevated rate of SCEs is comparable to that of BLM-deficient cells. Upon creating the double knock-out *RECQ5*^{-/-}/*BLM*^{-/-}, the authors could observe a normal growth rate, but a further increase in the rate of SCEs, compared to the single knockouts. Their data imply that *RECQ5* and BLM have nonredundant roles in suppressing SCEs. It is not clear, however, in what kind of pathway *RECQ5* would function to suppress SCEs (142). These results differ somewhat from those obtained from the chicken DT40 B-cell line, but probably mouse cells are a better model, as the murine and the human *RECQ5* share 79% homology.

Abbreviations

Abbreviation	Explanation
4NQO	4-nitroquinoline 1-oxide
ALT	Alternative lengthening of telomeres
ATP	Adenosine-triphosphate
BER	Base excision repair
BLM	Bloom syndrome protein
bp	Base pairs
BS	Bloom syndrome
eto	Etoposide
DHJ	Double Holliday junction
DSB	Double strand break
dsDNA	Double-stranded DNA
ES cells	Embryonic stem cells
FA	Fanconi anemia
FRET	Fluorescence resonance energy transfer
GTP	Guanosine-triphosphate
HJ	Holliday junction
HSV	Herpes simplex virus
HU	Hydroxyurea
HDAC	Histone deacetylase
HRDC	Helicase and Rnase D C-terminal domain
IgA	Immunoglobulin A
IgM	Immunoglobulin M
MMC	Mitomycin C
MMS	Methyl methanesulfonate
MMR	Mismatch repair
MRN	The MRE11/RAD50/NBS1 complex
MutS α	The MSH2/MSH6 heterodimer
MutS β	The MSH2/MSH3 heterodimer
MutL α	The MLH1/PMS2 heterodimer
NLS	Nuclear localisation signal
nt	Nucleotides
NTP	Nucleoside-triphosphate

PCNA	Proliferating cell nuclear antigen
PML	Premyelocytic leukemia protein
RFC	Replication factor C
RPA	Replication protein A
RTS	Rothmund-Thomson syndrome
SCE	Sister-chromatid exchange
SF	Superfamily
ssDNA	Single-stranded DNA
SUMO	Small ubiquitin-like modifier
TSA	Trichostatin A
Ub	Ubiquitin
UV	Ultraviolet
WH	Winged helix
WHIP	Werner helicase interacting protein
WRN	Werner syndrome protein

Bloom syndrome protein forms an oligomeric ring structure and belongs to a group of DNA helicases showing extensive homology to the *Escherichia coli* DNA helicase RecQ, a suppressor of illegitimate recombination. After over-production in *E. coli*, we have purified the RecQ core of BLM consisting of the DEAH, RecQ-Ct and HRDC domains (amino acid residues 642–1290). The BLM^{642–1290} fragment could function as a DNA-stimulated ATPase and as a DNA helicase, displaying the same substrate specificity as the full-size protein. Gel-filtration experiments revealed that BLM^{642–1290} exists as a monomer both in solution and in its single-stranded DNA-bound form, even in the presence of Mg²⁺ and ATPγS. Rates of ATP hydrolysis and DNA unwinding by BLM^{642–1290} showed a hyperbolic dependence on ATP concentration, excluding a co-operative interaction between ATP-binding sites. Using a λ Spi[−] assay, we have found that the BLM^{642–1290} fragment is able to partially substitute for the RecQ helicase in suppressing illegitimate recombination in *E. coli*. A deletion of 182 C-terminal amino acid residues of BLM^{642–1290}, including the HRDC domain, resulted in helicase and single-stranded DNA-binding defects, whereas kinetic parameters for ATP hydrolysis of this mutant were close to the BLM^{642–1290} values. This confirms the prediction that the HRDC domain serves as an auxiliary DNA-binding domain. Mutations at several conserved residues within the RecQ-Ct domain of BLM reduced ATPase and helicase activities severely as well as single-stranded DNA-binding of the enzyme. Together, these data define a minimal helicase domain of BLM and demonstrate its ability to act as a suppressor of illegitimate recombination.

Introduction

Helicases are motor proteins that are characterized by the ability to unwind nucleic acid duplexes (DNA–DNA, DNA–RNA and RNA–RNA) in a

reaction coupled to the hydrolysis of NTPs.^{1–4} Helicases perform a variety of important tasks in nucleic acid metabolism, ranging from a simple strand separation at the replication fork to more sophisticated processes, such as migration of Holliday junctions.^{5,6}

Mechanistically, there are two classes of helicases: those that translocate along a nucleic acid strand in a 3' to 5' direction; and those that operate with the opposite polarity. Based on amino acid sequence homology, helicases have been grouped into five superfamilies (SF1–SF5).⁷ Most 3'–5' DNA helicases are members of SF1 or SF2. These two superfamilies have similar sets of conserved motifs, and the proteins are generally considered to be monomeric. However, the oligomeric state of

Abbreviations used: ATPγS, adenosine 5'-O-(3-thio-triphosphate); BS, Bloom syndrome; CBD, chitin-binding domain; DSB, double-strand break; dsDNA, double-stranded DNA; EMSA, electrophoretic mobility-shift assay; HRDC, helicase and RNaseD C-terminal; P_i, inorganic phosphate; RecQ-Ct, RecQ C-terminal; SCE, sister chromatid exchanges; ssDNA, single-stranded DNA; WS, Werner syndrome.

E-mail address of the corresponding author: pjanscak@imr.unizh.ch

the functional form of these enzymes has been debated, with both monomeric and oligomeric models being proposed.^{8–12} The 5'-3' DNA helicases belong to SF4 and SF5. They are characterized by fewer conserved motifs and generally form hexameric rings.¹³

The RecQ helicase family belongs to SF2 and includes enzymes that have extensive homology to the 3'-5' DNA helicase RecQ of *Escherichia coli*. This enzyme is involved in processing nascent DNA at blocked replication forks prior to the resumption of DNA synthesis and in suppressing illegitimate recombination.^{14,15} Interestingly, prokaryotes and unicellular eukaryotes possess only a single RecQ helicase, while several RecQ homologues are present in multi-cellular organisms.¹⁶ In humans, five RecQ homologues have been identified thus far. Mutations in three of them have been shown to be associated with autosomal recessive disorders characterized by genomic instability and cancer predisposition. Mutations in BLM result in Bloom syndrome (BS); mutations in WRN result in Werner syndrome (WS); and mutations in RecQL4 result in Rothmund-Thomson syndrome (RTS).^{17–19} Genomic instability in BS is evidenced by chromosome breaks, gaps and, most typically, by high rate of sister chromatid exchanges (SCE).²⁰ Cells from WS and RTS individuals display an increased rate of gross chromosomal rearrangements.²⁰ Mutations in RecQ homologues in other eukaryotic organisms also are associated with increased rates of chromosomal abnormalities.^{21,22}

Although cellular phenotypes of mutants suggest that RecQ DNA helicases act as suppressors of illegitimate recombination, exact DNA transactions mediated by these enzymes to maintain genomic stability remain elusive. Illegitimate recombination takes place between sequences of little or no homology exposed upon exonucleolytic processing of DNA double-strand breaks (DSBs) and it results in DNA rearrangement such as deletions, translocations, duplications or inversions.^{23,24} The observations that several RecQ helicases could promote branch migration of Holliday junctions led to the proposal that these enzymes remove Holliday junctions formed at stalled replication forks and thus suppress induction of DSBs through the action of a resolvase.⁶ WRN was shown to facilitate copying of tetraplex and hairpin structures of the d(CGG) trinucleotide repeat sequence by DNA polymerase δ , suggesting another mechanism that would minimize formation of DSBs at replication forks stalled by unusual DNA secondary structures.²⁵ Furthermore, there is evidence suggesting that RecQ DNA helicases promote non-mutagenic repair of DSBs, perhaps by inhibiting extensive exonucleolytic processing of DSBs or by dissociating intermediates of illegitimate recombination produced by single-strand annealing at sites of micro-homology.^{24,26,27}

All RecQ family members contain a DEAH helicase domain characterized by a set of seven amino acid sequence motifs that are present in other SF2

helicases. Mutagenesis and structural studies of a number of SF1 and SF2 helicases demonstrated that these motifs are responsible for coupling of ATP hydrolysis to DNA binding, translocation and unwinding.^{8,28–31} In addition, all RecQ helicases contain a C-terminal extension that can be divided into two domains.³² The proximal domain, called the RecQ-Ct (RecQ C-terminal) domain, is unique to the family. The distal domain is present also in RNaseD and its eukaryotic homologues, and is called the HRDC (helicase and RNaseD C-terminal) domain. A recent NMR structure of the HRDC domain of Sgs1 (the single RecQ homologue in *Saccharomyces cerevisiae*) suggested that this domain might function as an auxiliary DNA-binding domain in a manner similar to that of its structural homologue, domain 1B in PcrA.³³ The role of the RecQ-Ct domain in the helicase function remains to be determined. The eukaryotic members of the RecQ family usually have additional N and C-terminal domains that flank the RecQ core, which show little or no sequence homology and vary considerably in size between different RecQ members.³⁴ These divergent domains are involved in interactions with other proteins and thus most probably serve to differentiate functionally between the multiple RecQ helicases present in higher eukaryotes.³⁴

Size-exclusion chromatography and electron microscopic examination of BLM indicated that it forms predominantly a hexameric ring structure.³⁵ BLM oligomerization is mediated by the N-terminal part of the protein.³⁶ Similarly, a purified N-terminal exonuclease domain of the WRN protein was found to exist in a trimer/hexamer equilibrium, which was shifted towards the hexameric species upon addition of a DNA substrate.³⁷ This suggests that the full-size WRN protein may also form a hexamer. Moreover, steady-state kinetic analysis of the helicase activity of the *E. coli* RecQ helicase suggested that the enzyme may act as an oligomer, perhaps a trimer.³⁸

Here, we report biochemical characteristics of a recombinant fragment of the Bloom syndrome protein encompassing the amino acid residues 642–1290, which includes the entire RecQ homology region of BLM. We have found that this fragment exists as a monomer both in solution and in a form bound to a 30mer oligonucleotide, even in the presence of adenosine 5'-O-(3-thiotriphosphate) (ATP γ S) and Mg²⁺, and can function as a DNA-stimulated ATPase as well as a DNA helicase, displaying the same substrate specificity as the full-size protein. This indicates that the oligomeric ring structure formed by BLM is not essential for the helicase activity of the enzyme. Using a λ Spi⁻ assay, we have found that expression of BLM^{642–1290} in an *E. coli* strain carrying a *recQ* mutation partially reduced the elevated illegitimate recombination observed in this strain, suggesting that the RecQ function to suppress illegitimate recombination has been conserved throughout evolution. Furthermore, we have investigated the roles of the

RecQ-Ct and HRDC domains of BLM in helicase activity of the enzyme by mutational analysis. Our data suggest that the RecQ-Ct domain may be involved in coupling of DNA binding to ATP hydrolysis, whereas the HRDC domain may serve as an auxiliary DNA-binding domain.

Results

Expression, purification and determination of the oligomeric state of BLM^{642–1290}

The region of the *BLM* cDNA encoding the RecQ portion of BLM (amino acid residues 642–1290, Figure 1(a)) was cloned in the pTXB3 vector to construct a translational fusion of this fragment with a C-terminal Mxe intein and chitin-binding domain, which serves as a self-cleaving affinity tag. Expression of this construct in the BL21-CodonPlus (DE3)-RIL strain yielded large amounts of the fusion protein in soluble form (Figure 1(b)). Usage of the RIL codon plus strain significantly increased the level of protein expression when compared to BL21(DE3) (data not shown). The BLM^{642–1290} protein was purified to more than 95% homogeneity by combining affinity purification on a chitin column with subsequent chromatography on heparin

and CM-Sepharose columns (see Materials and Methods). This procedure yielded typically 1–1.5 mg of pure protein per 1 g of cell paste.

In order to characterize the oligomeric state of BLM^{642–1290}, we carried out size-exclusion chromatography using a Superdex 200 column. We determined apparent molecular masses of BLM^{642–1290} in solution and in a form bound to a 30mer oligonucleotide both in the absence and presence of the poorly hydrolyzable analogue of ATP, ATP γ S, and Mg²⁺ (Table 1). The BLM^{642–1290} protein alone was found to elute in a single peak corresponding to a molecular mass of 66.8 kDa and in the presence of ATP γ S/Mg²⁺ in a peak corresponding to 69.3 kDa. As the predicted molecular mass of BLM^{642–1290} is 74.1 kDa, these data suggest that BLM^{642–1290} exists as a monomer in solution. Addition of a 30mer oligonucleotide to BLM^{642–1290} (at a BLM to DNA molar ratio of 6) in the absence and in the presence of ATP γ S/Mg²⁺ resulted in peaks corresponding to molecular masses of 103.3 kDa and 104.6 kDa, respectively. Since the 30mer oligonucleotide alone eluted from the column at a molecular mass of 33 kDa, these data suggest that BLM^{642–1290} exists as monomer in its single-stranded DNA (ssDNA)-bound form.

Biochemical characterization of the BLM^{642–1290} fragment

The purified BLM^{642–1290} fragment was first tested for its ability to hydrolyze ATP in the presence of various DNA effectors, including circular M13mp18 ssDNA, synthetic 43mer oligonucleotide and plasmid double-stranded DNA (dsDNA). ATPase activity was monitored by measuring the production of inorganic phosphate (P_i) using a malachite green assay (see Materials and Methods). As shown in Figure 2(a), BLM^{642–1290} exhibited a strong DNA-dependent ATPase activity. The rate of ATP hydrolysis in the presence of ssDNA was higher than that in the presence of plasmid dsDNA. Only a weak ATPase activity was observed in the absence of a DNA effector.

The ATPase reaction catalyzed by BLM^{642–1290} in the presence of circular M13mp18 ssDNA displayed classical Michaelis–Menten kinetics over a range of ATP concentrations from 10 μ M to 2 mM (Figure 2(b)). The steady-state kinetic parameters

Figure 1. Structure and purification of BLM^{642–1290}. (a) A schematic of the Bloom syndrome protein demonstrating the location of the DEAH helicase, RecQ-Ct and HRDC domains. The locations of the protein–protein interaction regions for DNA topoisomerase III α (TOPO III α), MLH1 and RAD51 are indicated above this scheme by black lines. A schematic of the BLM^{642–1290} fragment is shown below. (b) SDS-PAGE of fractions from purification of BLM^{642–1290}. The protein was expressed and purified as described in Materials and Methods. Samples were analyzed on a 10% polyacrylamide gel, which was stained with Coomassie brilliant blue. Lane 1, protein size markers; lane 2, total cell extract; lane 3, soluble part of cell extract; lane 4, pooled fractions from chitin column; lane 5, pooled fractions from heparin column; lane 6, pooled fractions from a CM-Sepharose column.

Table 1. Molecular masses of free and DNA-bound forms of BLM^{642–1290} in the presence and in the absence of ATP γ S/Mg²⁺ determined by gel-filtration

Sample	Apparent molecular mass (kDa)
30mer	33.0
BLM	66.8
BLM + 30mer	103.3
BLM + Mg ²⁺ + ATP γ S	69.3
BLM + Mg ²⁺ + ATP γ S + 30mer	104.6

The predicted molecular mass of BLM^{642–1290} is 74.1 kDa.

Figure 2. ATPase activity of BLM⁶⁴²⁻¹²⁹⁰. (a) Time-course of ATP hydrolysis by 20 nM BLM⁶⁴²⁻¹²⁹⁰ in the presence of various DNA co-factors including M13mp18 ssDNA (circle), pTZ18R plasmid dsDNA (upwards pointing triangle), 43mer synthetic oligonucleotide (square) and no DNA (downwards pointing triangle). In each reaction, DNA was present at a concentration of 25 $\mu\text{g}/\text{ml}$ and ATP was 2 mM. (b) Dependence of the initial rate of ATP hydrolysis by 20 nM BLM⁶⁴²⁻¹²⁹⁰ in the presence of M13mp18 ssDNA (25 $\mu\text{g}/\text{ml}$) on ATP concentration. Reactions were carried out in buffer H at 37 °C and quantified as described in Materials and Methods. The lines in (a) correspond to a fit by an exponential equation:

$$Y = Y_{\max}(1 - \exp(-kX))$$

where Y is the concentration of the reaction product, X is time and k is the rate constant. The line in (b) corresponds to a fit by Michaelis-Menten equation:

$$Y = Y_{\max}X/(K_M + X)$$

where Y is the initial reaction rate, X is the concentration of substrate and K_M is the Michaelis-Menten constant. Each value represents the mean of at least three independent measurements.

of the ATPase reaction, k_{cat} and K_M , were 22.14 s^{-1} and 77.3 μM , respectively. The fact that the enzyme kinetic curve is hyperbolic rather than sigmoidal suggests that ATP hydrolysis by BLM⁶⁴²⁻¹²⁹⁰ is not a co-operative reaction.

The helicase activity of BLM⁶⁴²⁻¹²⁹⁰ was first tested on a partial DNA duplex substrate compris-

ing a 44mer radiolabeled oligonucleotide annealed to circular M13mp18 ssDNA. This substrate was incubated with increasing amounts of BLM⁶⁴²⁻¹²⁹⁰ in the presence of ATP, which was followed by analysis of the reaction products on a non-denaturing 15% polyacrylamide gel. Figure 3(a) shows that BLM⁶⁴²⁻¹²⁹⁰ indeed possesses a DNA-unwinding activity, resulting in displacement of the radiolabeled oligonucleotide from M13mp18 ssDNA.

To estimate the affinity of BLM⁶⁴²⁻¹²⁹⁰ helicase for ATP, the initial rate of BLM⁶⁴²⁻¹²⁹⁰-mediated unwinding of 25 bp partial M13 duplex was measured over a range of concentrations of ATP from 5 μM to 2 mM. The data displayed a hyperbolic dependence on ATP concentration with a $K_{1/2}$ value of 31.8 μM (Figure 3(b)). The hyperbolic nature of the curve argues against a co-operativity in the helicase reaction of BLM⁶⁴²⁻¹²⁹⁰ with respect to ATP concentration.

To compare the substrate specificity of the BLM⁶⁴²⁻¹²⁹⁰ fragment to that of the full-size protein, we have examined the ability of these proteins to unwind various 5' end-labeled synthetic DNA structures with a common duplex region sequence, including blunt-ended duplex, 3' ssDNA-tailed duplex, forked duplex with two non-complementary single-stranded arms (splayed arm) and blunt-ended duplexes containing either a nick or a 5'-ssDNA flap (20 nt) in the central part of the DNA molecule. The last two DNA molecules have not been tested as substrates for BLM thus far. Like the full-size BLM protein, the BLM⁶⁴²⁻¹²⁹⁰ fragment could unwind both 3'-ssDNA-tail duplex and splayed arm, with the latter being unwound more efficiently than the former (Figure 3(c)). The blunt-ended duplex was not unwound by either protein. In contrast, both proteins could efficiently unwind the 5' flap structure to extents similar to those of the splayed arm, releasing the labeled 5' flap oligonucleotide (Figure 3(c)). The nicked duplex was a much poorer substrate for unwinding by both enzymes compared to the 5' flap duplex (Figure 3(c)), indicating a role of the 5'-ssDNA flap in the initiation of duplex unwinding.

The BLM helicase was shown to disrupt synthetic immobile four-way DNA junctions, which resemble Holliday junctions.³⁹ To investigate whether the BLM⁶⁴²⁻¹²⁹⁰ fragment possesses such an activity, a four-way junction substrate prepared by annealing of 50mer oligonucleotides, of which one was 5' end-labeled, was incubated with increasing amounts of BLM⁶⁴²⁻¹²⁹⁰. Figure 3(d) shows that BLM⁶⁴²⁻¹²⁹⁰ was able to disrupt four-way junctions to the component single strands, as is evident from the appearance of the free radiolabeled oligonucleotide. As observed with the full-size BLM protein, the unwinding of four-way junctions by BLM⁶⁴²⁻¹²⁹⁰ resulted in the accumulation of three-stranded and two-stranded species, suggesting that these species are reaction intermediates.³⁹ The presence of traces of these species in untreated DNA substrate is most probably due to spontaneous

Figure 3. DNA helicase activity of BLM⁶⁴²⁻¹²⁹⁰. (a) Unwinding of 44 bp partial M13 duplexes by BLM⁶⁴²⁻¹²⁹⁰. Reaction mixtures (10 μ l) in buffer H contained 0.5 nM DNA, 2 mM ATP and the indicated amounts of BLM⁶⁴²⁻¹²⁹⁰. The reactions were initiated with enzyme and incubated at 37 °C for 30 minutes prior to termination by adding 0.5 reaction volume of buffer S. Samples were analyzed by electrophoresis in non-denaturing 15% polyacrylamide gel followed by autoradiography. (b) Dependence of the initial rate of unwinding of 0.5 nM 25 bp partial M13 duplex by 20 nM BLM⁶⁴²⁻¹²⁹⁰ on the concentration of ATP. Reaction rates were measured in buffer H at 37 °C as described in Materials and Methods for concentrations of ATP ranging from 10 μ M to 2000 μ M. Each value represents the mean of at least three independent measurements. The line in the graph corresponds to a fit by the Michaelis-Menten equation (see the legend to Figure 2). (c) Comparison of the helicase activities of BLM⁶⁴²⁻¹²⁹⁰ and BLM^{FS} (full-size BLM) on blunt-ended duplex (lanes 1–4), 3'-ssDNA-tailed duplex (lanes 5–8), splayed arm (lanes 9–12), 5'-ssDNA-flap duplex (lanes 13–16) and nicked duplex (lanes 17–20). Reaction mixtures (10 μ l) in buffer H contained 1 nM DNA substrate, 2 mM ATP and 20 nM enzyme. Reactions were carried out and analyzed as described for (a). The triangles mark the lanes that contain heat-denatured DNA. Note that the 5'-flap substrate contains a small fraction of splayed arm, which is due to incomplete annealing of the C₁₉ oligonucleotide. (d) Unwinding of the synthetic four-way junction by BLM⁶⁴²⁻¹²⁹⁰. Reaction mixtures (10 μ l) in buffer H contained 1 nM DNA substrate, 2 mM ATP and the indicated amounts of BLM⁶⁴²⁻¹²⁹⁰. Reactions were carried out and analyzed as described for (a). Positions of four-way junction substrate, three-stranded, two-stranded and single-stranded products are indicated to the right. DNA substrates were prepared as described

dissociation of the four-way structure following electroelution from polyacrylamide gel.

Together, these data show that the BLM⁶⁴²⁻¹²⁹⁰ fragment can function as an ATP-dependent DNA helicase with the same substrate specificity as the full-size protein. Moreover, the lack of co-operativity in both ATPase and helicase reactions (with respect to ATP concentration) in combination with the gel-filtration data argues that the BLM⁶⁴²⁻¹²⁹⁰ helicase may function as a monomer.

The BLM⁶⁴²⁻¹²⁹⁰ helicase can suppress elevated illegitimate recombination in *E. coli* *recQ* mutant

In order to obtain further functional characteristics of BLM⁶⁴²⁻¹²⁹⁰, we asked whether it is able to substitute *in vivo* for the *E. coli* RecQ helicase in suppressing illegitimate recombination. Using the λ Spi⁻ assay, it has been demonstrated that *E. coli* *recQ* mutations enhance frequency of spontaneous and UV-induced illegitimate recombination, indicating that RecQ plays a suppressive role in illegitimate recombination.¹⁵ In the λ Spi⁻ assay, the frequency of formation of specialized λ bio transducing phages, which result from abnormal excision of the chromosome by illegitimate recombination, is measured.⁴⁰ Most of the λ bio transducing phages lack the *red-gam* region of λ phage and show the Spi⁻ phenotype, which is the ability to form plaques on a lawn of *E. coli* P2 lysogen. On the other hand, normal λ phages cannot grow in P2 lysogen. Therefore, the frequency of illegitimate recombination can be calculated as a ratio of the number of Spi⁻ phages to the number of total phages in a given lysate. To examine whether the BLM⁶⁴²⁻¹²⁹⁰ helicase can suppress the hyper-recombination phenotype of RecQ-deficient cells, the corresponding region of the BLM cDNA was cloned into pBluescript SK(+) under control of the *lac* promoter. The resulting plasmid construct was introduced into the HI2776 Δ *recQ101* λ cl857 lysogen and the frequencies of the λ Spi⁻ phage formation in this strain prior to and after UV irradiation were compared with those displayed by the Δ *recQ101* mutant transformed with the pBluescript SK(+) vector. We found that BLM⁶⁴²⁻¹²⁹⁰ significantly reduced the rate of illegitimate recombination in the Δ *recQ101* mutant under both the non-irradiated (tenfold) and the irradiated (4.1-fold) conditions, although it did not restore the wild-type levels completely (Table 2). Interestingly, the wild-type strain (HI1162 λ cl857 lysogen) harboring the BLM plasmid showed a higher frequency of λ Spi⁻ phage formation than the wild-type strain harboring the pBluescript SK(+) vector (Table 2), suggesting that the BLM fragment may also have a negative effect on the DNA metabolism in *E. coli*.

in Materials and Methods. The asterisks (*) indicate the location of the radioactive label.

Table 2. Effect of BLM^{642–1290} on spontaneous and UV-induced illegitimate recombination in the wild-type and *recQ* mutation background

Strain	UV dose (J/m ²)	λ Spi ⁻ phages (10 ⁻⁹) per total λ phage (SE)	Relative frequency λ Spi ⁻ to control	Burst size
Wild-type ^a [pBluescript SK(+)]	0	1.0 (0.33)	1	114
Wild-type ^a [pJP79 (BLM ⁺)]	0	12 (1.0)	12	91
Δ recQ101 ^b [pBluescript SK(+)]	0	130 (16)	1	52
Δ recQ101 ^b [pJP79 (BLM ⁺)]	0	13 (1.5)	0.1	91
Wild-type ^a [pBluescript SK(+)]	25	80 (4.7)	1	95
Wild-type ^a [pJP79 (BLM ⁺)]	25	120 (26)	1.5	85
Δ recQ101 ^b [pBluescript SK(+)]	25	1200 (100)	1	53
Δ recQ101 ^b [pJP79 (BLM ⁺)]	25	290 (21)	0.24	98

The frequency of Spi⁻ phages per total phages was measured as described in Materials and Methods. Values are the average of four independent measurements. (SE) indicates the standard error of the mean. Burst size is the number of total phages per cell.

^a HI1162 λ cl857 lysogen.

^b HI2776 Δ recQ101 :: cat λ cl857 lysogen.

Together, these results indicate that the BLM fragment can indeed function as a suppressor of spontaneous and UV-induced illegitimate recombination in *E. coli*, although the compensation of the *recQ* mutation was partial.

C-terminal deletion mutagenesis of BLM^{642–1290}

As mentioned above, the homology region of RecQ family members consists of the DEAH helicase, RecQ-Ct and HRDC domains. The DEAH helicase domain contains a set of seven amino acid sequence motifs that have been studied extensively in other SF1 and SF2 DNA helicases, and shown to mediate coupling of ATP hydrolysis to DNA translocation and unwinding.^{8,28–31} The roles of the RecQ-Ct and HRDC domains, which are present only in the RecQ family of DNA helicases, remain to be investigated. To address the importance of the RecQ-Ct and HRDC domains of BLM for the helicase activity of the enzyme, we have generated a series of C-terminal truncations of BLM^{642–1290}, including BLM^{642–1167}, BLM^{642–1108}, BLM^{642–1056}, BLM^{642–1036} and BLM^{642–997}, by cloning corresponding regions of the BLM cDNA into pTXB3 to construct translational fusions with a C-terminal Mxe intein and a chitin-binding domain. However, only one of those constructs, lacking the HRDC domain and a part of the linker connecting the HRDC and RecQ-Ct domains (BLM^{642–1108}) was found to produce stable soluble protein when expressed in the *E. coli* BL21 (RIL) strain. The shorter deletion variants lacking a part of or the entire RecQ-Ct domain were found to be insoluble when expressed as fusions with Mxe-CBD. The BLM^{642–1167} mutant ending at the beginning of the HRDC domain could not be expressed in *E. coli* BL21 (RIL), perhaps due to its sensitivity to degradation.

The BLM^{642–1108} variant was subjected to the same purification procedure as BLM^{642–1290}. However, it was not bound to the heparin column. Measuring steady-state parameters for ATP hydrolysis in the presence of a 43mer oligonucleotide revealed that the BLM^{642–1108} mutant displayed

nearly the same ssDNA-dependent ATPase activity as BLM^{642–1290} (Table 3). In contrast, it showed about threefold decrease in helicase activity on 25 bp partial M13 duplex substrate with respect to BLM^{642–1290} and even more pronounced defect in the ability to disrupt four-way junctions (Figure 4(a) and (b)). An electrophoretic mobility-shift assay (EMSA) employing 5' end-labeled 30mer oligonucleotide (also used for the S200 gel-filtration experiments) revealed that the BLM^{642–1108} mutant had reduced ssDNA binding activity dramatically as compared to BLM^{642–1290} (Figure 7).

Thus, the data from biochemical characterization of BLM^{642–1108} support the prediction that the HRDC domain serves as an auxiliary DNA-binding domain.³³

Site-directed mutagenesis of the RecQ-Ct domain

Because of the insolubility of BLM fragments lacking the RecQ-Ct domain, we examined the importance of this region using a site-directed approach. We altered several residues in this

Table 3. Steady-state kinetic parameters for ssDNA-dependent ATP hydrolysis by BLM mutants

Protein	k_{cat} (s ⁻¹)	k_{cat} decrease factor	K_m (μ M)	K_m (wt)/ K_m (mut)
Wild-type	25.79	1.00	63.5	1.00
R1038A	1.36	18.96	66.6	1.00
F1045A	4.76	5.42	62.8	0.99
E1047Q	18.62	1.39	59.0	0.93
E1047A	14.72	1.75	148.1	2.33
D1064N	23.48	1.10	74.0	1.17
D1064A	0.12	214.92	58.5	0.92
R1108A	25.97	0.99	51.2	0.81
K1125A	27.01	0.95	54.3	0.86
BLM ^{642–1108}	19.63	1.31	51.9	0.82

BLM^{642–1290} is referred to as wild-type in this table. The point mutants are derivatives of BLM^{642–1290}. ATPase reactions were carried out in the presence of 43mer oligonucleotide as described under Materials and Methods.

Figure 4. DNA helicase activity of the BLM⁶⁴²⁻¹¹⁰⁸ mutant. Unwinding of (a) 0.5 nM 25 bp partial M13 duplex and (b) 1 nM synthetic four-way junction by BLM⁶⁴²⁻¹²⁹⁰ (square) and BLM⁶⁴²⁻¹¹⁰⁸ (circle) as a function of protein concentration. DNA substrates were prepared as described in Materials and Methods. Reactions (10 μ l) were carried out in buffer H containing 2 mM ATP. After 30 minutes incubation at 37 °C, reaction products were quantified as described in Materials and Methods. The lines in the graphs are drawn just to guide the eye. Individual datum points represent the mean of at least three independent measurements.

domain that are conserved among RecQ family members (Figure 5(a)) and characterized the biochemical properties of the resulting mutant proteins. The following amino acid residues were chosen for mutagenesis of the BLM⁶⁴²⁻¹²⁹⁰ fragment: C1036, R1038, F1045, E1047, C1063, D1064 and C1066 (Figure 5(a)). We have created alanine mutants at all those residues. The acidic residues E1047 and D1064 were replaced also by a glutamine and an asparagine, respectively. The mutants were prepared in the same way as the wild-type enzyme. Under these conditions, all the three cysteine mutants exhibited a high level of susceptibility to degradation, being degraded almost completely following purification on the chitin column and were, therefore, not further analyzed.

Substitutions at all residues were found to impair the ssDNA-dependent ATPase activity of BLM⁶⁴²⁻¹²⁹⁰ (Table 3). Interestingly, at position 1064, the value of k_{cat} was found to be related to

the nature of the present residue. While the neutral D1064A mutant displayed a very poor k_{cat} value, the polar D1064N mutant had a k_{cat} value similar to that of the wild-type enzyme. (The same dependence was observed for helicase and ssDNA binding activities; see below.) All of the mutants had a K_M for ATP similar to that of the wild-type enzyme, with the exception of the E1047A mutant, which exhibited about twofold higher value of K_M than the wild-type enzyme (Table 3). The helicase activity of the mutants was measured using partial M13 duplex (25 bp) and four-way junction substrates. With the exception of the D1064N mutant, all mutants had reduced strand displacement activity on both substrates, with R1038A and D1064A mutants being affected most dramatically (Figure 6(a) and (b)). The ability of the BLM mutants to bind ssDNA was again investigated by EMSA using a 5' end-labeled 30mer oligonucleotide. Figure 7 shows that all mutants displayed a reduction in their affinity for ssDNA compared to BLM⁶⁴²⁻¹²⁹⁰ from about twofold decrease (in apparent K_d) for the D1064N mutant to more than 20-fold decrease for the D1064A mutant.

Together, these data indicate that the RecQ-Ct domain of BLM plays an important role in the helicase function of the enzyme.

Site-directed mutagenesis of the region connecting the RecQ-Ct and HRDC domains of BLM

Multiple sequence alignment of RecQ family members also reveals a number of conserved residues in the region connecting the RecQ-Ct and HRDC domains (Figure 5(b)). To investigate the importance of this region for helicase activity of BLM, we have produced single alanine mutants of BLM⁶⁴²⁻¹²⁹⁰ at R1108 and K1125, two highly conserved residues in this region. Biochemical characterization of these mutants indicated that they do not show significant differences from the wild-type enzyme in ATPase or helicase activities (Table 3 and Figure 6(b)), or in the ability to bind ssDNA (not shown). These data suggest that the defects observed in the BLM⁶⁴²⁻¹¹⁰⁸ mutant, which lacks a large part of this region, are rather due to the absence of the HRDC domain.

Discussion

In this work, we have characterized a recombinant fragment of the Bloom syndrome protein including the entire RecQ homology region and investigated the role of its RecQ-Ct and HRDC domains in the helicase activity of the enzyme.

Analysis of BLM⁶⁴²⁻¹²⁹⁰ using size-exclusion chromatography revealed that it exists as a monomer both in solution and in its ssDNA-bound form (in the presence and in the absence of ATP γ S/Mg²⁺) (Table 1). In contrast, the full-size

Figure 5. Amino acid sequence alignment of several RecQ helicases. The regions corresponding to (a) the RecQ-Ct domain and (b) the proximal part of the domain connecting the RecQ-Ct and HRDC domains are shown. The multiple alignment was performed with the program ClustalX and refined manually. The numbers at the end of each sequence correspond to the position of the last amino acid residue. Highly conserved amino acid residues are shadowed in grey. Amino acid substitutions generated in BLM⁶⁴²⁻¹²⁹⁰ are shown. The protein accession numbers used by the National Center for Biotechnology Information are: Sgs1, P35187; Rqh1, Q09811; RecQL1, NP_002898; WRN, NP_000544; BLM, A57570.

BLM protein forms an oligomeric ring structure in solution.³⁵ The oligomerization of BLM is mediated by the N-terminal region of the protein³⁶, which is absent in the BLM⁶⁴²⁻¹²⁹⁰ fragment. Since BLM⁶⁴²⁻¹²⁹⁰ retained all the enzymatic activities found in the full-size protein, including the ability to function as a structure-specific DNA helicase, it seems that the ring structure of BLM is probably required for other functions: perhaps it is involved in the formation of specific multiprotein-DNA repair complexes.

The rates of both ATP hydrolysis and DNA unwinding by BLM⁶⁴²⁻¹²⁹⁰ showed a hyperbolic dependence on ATP concentration (Figures 2(b) and 3(b)), which argues against a co-operative interaction between ATP-binding sites during unwinding and suggests that the enzyme may act as a monomer. This assumption may be supported by a hyperbolic nature of the dependence of DNA unwinding by BLM⁶⁴²⁻¹²⁹⁰ on enzyme concentration (Figure 4(a) and (b)). As mentioned above, however, the issue of the functional form of non-hexameric helicases has been debated over the last years. Studies of the PcrA (SF1) and RecG (SF2) helicases have led to suggestions that these enzymes as well as other SF1 and SF2 members function as monomeric helicases.^{8,41} In contrast, pre-steady-state kinetic studies of DNA unwinding by the UvrD and Rep helicases, SF1 members, of which the latter has been shown to be a structural homologue of PcrA,⁴² demonstrated that enzyme oligomers are required to initiate unwinding.^{10,11} Recent single-molecule studies employing fluorescence resonance energy transfer technique to

measure unwinding indicated that a Rep monomer can use ATP hydrolysis to move towards the junction between ssDNA and dsDNA (in agreement with the PcrA model), but then displays conformational fluctuations that do not lead to DNA unwinding.¹² DNA unwinding initiates only when the translocating enzyme interacts with additional enzyme molecule(s).¹² Similar studies will be required for RecQ DNA helicases to gain deeper insight into the mechanism of unwinding by these enzymes.

RecQ helicases mechanistically belong to the 3'-5' class of helicases that generally require the presence of a 3' single-stranded tail to initiate unwinding of a DNA duplex. However, our experiments revealed that BLM can unwind efficiently forked duplexes having 3' arm double-stranded and 5' arm single-stranded (5'-ssDNA-flap duplex), indicating that the enzyme does not essentially require the 3' tail to be single-stranded to initiate DNA unwinding on a forked duplex (Figure 3(c)). Recently, the WRN helicase also has been shown to possess such an activity.⁴³ Moreover, both BLM and WRN helicases can unwind synthetic four-way junctions with blunt-ended arms and are able to promote the movement of a branched point along a long stretch of dsDNA.^{6,39,44} Thus, it appears that the mode of DNA translocation and unwinding by RecQ helicases is different from that of the 3'-5' helicases such as PcrA which translocate along ssDNA to mediate duplex unwinding.⁸ On the basis of similarity in substrate specificity, one can predict that RecQ helicases may be mechanistically related to the RecG

Figure 6. DNA helicase activity of BLM⁶⁴²⁻¹²⁹⁰ point mutants. (a) Unwinding of 0.5 nM 25 bp partial M13 duplex by wild-type and mutant BLM⁶⁴²⁻¹²⁹⁰ proteins as a function of protein concentration. (b) Unwinding of 1 nM synthetic four-way junction by wild-type and mutant BLM⁶⁴²⁻¹²⁹⁰ proteins each at a concentration of 40 nM. DNA substrates were prepared as described in Materials and Methods. Reactions (10 μ l) were carried out in buffer H containing 2 mM ATP. After 30 minutes incubation at 37 $^{\circ}$ C, reaction products were quantified as described in Materials and Methods. The data shown represent the mean of at least three independent measurements.

helicase, which is believed to mediate strand separation *via* translocation on dsDNA.⁴⁵

A deletion of 182 C-terminal amino acid residues from the BLM⁶⁴²⁻¹²⁹⁰ fragment including the HRDC domain and a part of the region connecting this domain with the RecQ-Ct domain substantially reduced the helicase activity of the enzyme on both partial duplex and four-way junction substrates (Figure 4(a) and (b)). Detailed analysis of the BLM⁶⁴²⁻¹¹⁰⁸ mutant revealed that it had a severe defect in the ability to bind ssDNA (Figure 7), whereas its kinetic parameters for ATP hydrolysis at saturating concentrations of ssDNA were close to the BLM⁶⁴²⁻¹²⁹⁰ values (Table 3). Thus, it appears that the deleted region significantly contributes to ssDNA binding but plays no direct role in ATP hydrolysis by the enzyme. The characteristics of the BLM⁶⁴²⁻¹¹⁰⁸ mutant are consistent with the pre-

diction that the HRDC domain serves as an auxiliary DNA-binding domain, which was made on the basis of similarity of the three-dimensional structure of the Sgs1 HRDC domain to an ssDNA-binding domain of the human DNA polymerase β or the domain 1B of PcrA.³³ However, the BLM⁶⁴²⁻¹¹⁰⁸ fragment also lacks a large part of the region connecting the RecQ-Ct and HRDC domain that contains a number of amino acid residues conserved among RecQ family members, raising the possibility that the absence of this region rather than the absence of the HRDC domain is responsible for the observed defects. Nevertheless, we have found that single alanine substitutions at two highly conserved basic residues, R1108 and K1125 of BLM located in this region, had no effect on the activity of BLM⁶⁴²⁻¹²⁹⁰, supporting the assumption that the defects of the BLM⁶⁴²⁻¹¹⁰⁸ mutant are due to the absence of the HRDC domain. A recombinant fragment of the Sgs1 helicase ending at the beginning of the HRDC domain failed to bind to a synthetic oligonucleotide, although it was able to function as an ATP-dependent DNA helicase.⁴⁶ Moreover, the small isoform of the *Drosophila melanogaster* RecQ5 helicase containing only the DEAH and RecQ-Ct domains showed significantly reduced DNA helicase activity compared to the large RecQ5 isoform, which contains the entire RecQ homology region, whereas the ATPase characteristics of these proteins were quite similar.^{47,48} Thus, all these findings suggest that the HRDC domain of RecQ helicases is involved in modulating the helicase activity of the enzyme through ssDNA binding, but is not absolutely required for the activity.

Biochemical characterization of BLM⁶⁴²⁻¹²⁹⁰ mutants at several conserved amino acid residues in the RecQ-Ct domain demonstrated that this domain is essential for the helicase activity of the enzyme (Figure 6). In particular, the R1038A, F1045A and D1064A mutants exhibited severe helicase defects. All alanine mutants displayed reduction in both ATP hydrolysis and ssDNA binding of magnitudes similar to those of the reduction in their helicase activity (compare Figure 6, Figure 7 and Table 3). Since DNA-dependent ATPase activity is a prerequisite of the DNA-unwinding function of the enzyme, ATPase defects of these mutants seem to be the cause of their helicase defects. It is less likely that the R1038, F1045 and D1064 residues are involved in DNA binding directly, because in such a scenario mutants would not exhibit significant ATPase defects under conditions of a saturating concentration of DNA. Instead, it is possible that the mutations at R1038, F1045 and D1064 induced local conformational changes in the protein that impaired coupling between DNA binding and ATPase activities of the enzyme or that these residues are involved directly in coupling of these activities.

Modeling of BLM structure using the crystal structure of the PcrA helicase as a template revealed that the DEAH domain of BLM consists

Figure 7. Electrophoretic mobility-shift assays of wild-type and mutant forms of BLM⁶⁴²⁻¹²⁹⁰. Proteins at the concentrations indicated were incubated with 0.5 nM 5' end-labeled, single-stranded 30mer in buffer B at room temperature for 20 minutes. Bound and free DNA were separated by electrophoresis through a non-denaturing 15% polyacrylamide gel and visualized using a PhosphorImager. Positions of free DNA and DNA-protein complexes are indicated on the right by arrowheads. Asterisks (*) indicate the positions of the wells.

of two RecA-like subdomains that are found in all SF1 and SF2 helicases for which structural information is available.⁴⁹ The cleft between these domains forms the ATP-binding site, with residues from seven helicase signature motifs mediating protein-nucleotide interactions.^{8,41,42} The structures showed also that DNA is bound along a groove on the top of the RecA-like domains and that the cleft closes and opens in response to ATP binding and hydrolysis, which suggested a mechanism for how protein translocates along DNA.⁸ It has been postulated that the RecA domains of SF1 and SF2 helicases represent the motor capable of translocating along DNA, and that the additional, diverse domains are determinants of the specificity of the enzyme.⁴ Thus, the domains 1B and 2B of PcrA are thought to be involved in destabilization of DNA duplex ahead of the motor translocating along ssDNA.⁶ The N-terminal domain of RecG, forming a large fold that is divided into three subdomains linked to the C-terminal RecA-like motor by a long helix, was shown to bind to a three-way DNA junction in a manner that would allow duplex separation.⁴¹ Thus, it is tempting to speculate that the region C-terminal to the DEAH domain of RecQ helicases including the RecQ-Ct and the HRDC domains have such a "specificity" function. Structural studies of a RecQ family member combined with biochemical analysis of mutants will certainly clarify this issue. The recombinant fragment of BLM described here seems to be a good candidate for these studies, since it can be prepared in large amounts at a high level of purity.

The fact that the BLM⁶⁴²⁻¹²⁹⁰ fragment could reduce the frequency of the λ Spi⁻ phage formation in a *recQ* mutant (Table 2) suggests that the RecQ function to suppress illegitimate recombination

has been conserved throughout the evolution from bacteria to humans. In *E. coli*, RecQ plays a role in suppression of RecET-mediated illegitimate recombination.^{15,24} It has been proposed that the RecQ helicase may unwind intermediates of the DNA end-joining reaction that involves annealing of 3' single-stranded tails, generated by the RecE-mediated exonucleolytic processing of a DSB, at sites of microhomology.²⁴ BLM has been shown to unwind forked DNA duplexes efficiently,³⁹ suggesting that it may indeed act on intermediates of illegitimate recombination to promote non-mutagenic repair of DSBs. However, experiments using mutants in the chicken cell line DT40 suggested that these DNA transactions are mediated rather by the WRN helicase, whereas BLM is probably involved in restarting DNA replication at stalled replication forks, which prevents generation of DSBs.²² However, recent evidence from plasmid rejoining assays using BLM proficient and deficient cell extracts demonstrated that BLM can suppress mutagenic repair of DSBs by illegitimate recombination,²⁶ suggesting an overlap between cellular functions of BLM and WRN. Our data support this assumption.

In contrast to the suppressive effect of the BLM fragment in a *recQ* mutant, its over-expression in the wild-type strain rather enhanced illegitimate recombination. A similar effect has been observed following over-expression of the DnaB helicase in *E. coli*.⁵⁰ A model has been proposed for initiation of illegitimate recombination in which over-production of DnaB helicase results in excessive DNA unwinding at replication forks and induction of DSBs.⁵⁰ A similar scenario might happen in the case of high levels of BLM, as it efficiently unwinds forked DNA duplexes.³⁹

Materials and Methods

DNA manipulations

All restriction and other DNA-modifying enzymes were purchased from New England Biolabs (NEB). The pJP71 expression vector was constructed by a PCR amplification of the region of *BLM* cDNA comprising the codons 642–1290 with primers introducing *NcoI* and *SapI* sites, respectively, and inserting the PCR product after digestion with *NcoI* and *SapI* between the *NcoI* and *SapI* sites in pTXB3 (NEB). This resulted in a translational fusion of BLM^{642–1290} with a self-cleaving affinity tag composed of the Mxe intein and a chitin-binding domain (CBD) present in pTXB3. An additional methionine residue was introduced between the BLM fragment and the intein according to the manufacturer's instructions. The plasmids pJP71S1167, pJP71S1108, pJP71S1056, pJP71S1036, pJP71S997 producing the C-terminal truncated variants of BLM^{642–1290}: BLM^{642–1167}, BLM^{642–1108}, BLM^{642–1056}, BLM^{642–1036} and BLM^{642–997}, respectively, as Mxe–CBD fusions were constructed in the same way as pJP71. All constructs were verified by sequencing to eliminate any possible mutations introduced by PCR. An origin repair method was employed for site-directed mutagenesis of BLM.^{51,52} Mutagenesis was performed using the plasmid pJP74, a derivative of pGLamB⁵² in which the *XbaI*–*BamHI* fragment containing the *lamB* gene was replaced by the *XbaI*–*BamHI* fragment of pJP71 encoding for the BLM^{642–1290}–intein–CBD fusion. For production of mutants, the resulting point mutations were transferred to pJP71 by replacing the *XbaI*–*BamHI* region in this plasmid with the corresponding *XbaI*–*BamHI* fragments from the mutant derivatives of pJP74. The plasmid pJP79 was constructed by introducing the *XbaI*–*BsaBI* fragment of pJP71 encoding for BLM^{642–1290} into pBluescript SK(+) digested with *XbaI* and *BamHI*. The *BamHI* end of the pBluescript SK(+) vector was filled in using Klenow fragment in this construction. In pJP79, BLM^{642–1290} is under control of the *lac* promoter and, as in pJP71, contains an additional methionine codon at the C terminus, which is followed by a TGA stop codon.

λ Spi[−] assay

HI2776 Δ*recQ101* :: *cat* λ *cl857* lysogen was constructed by transduction of HI1162 λ *cl857* lysogen⁵³ with P1 phage prepared from N1126 Δ*recQ101* :: *cat* (kindly provided by Dr J. Kato). The HI1162 and HI2776 strains were transformed with either pBluescript SK(+) or pJP79. The frequency of the λ Spi[−] phages in these strains was measured as described.⁴⁰ Briefly, cells were grown to 2 × 10⁸ cells/ml at 30 °C in λYP broth containing 20 μg/ml of ampicillin. If necessary, 2 ml of the culture was irradiated with a UV lamp (15 W) at a wavelength of 254 nm. Immediately after UV irradiation, the thermal induction of λ phage was carried out by incubation at 42 °C for 15 minutes with aeration. The culture was then incubated at 37 °C for two hours and the phage lysate was prepared. The titer of Spi[−] phage was measured by plating on *E. coli* WL95 P2 lysogen. The titer of total phage was measured by plating on *E. coli* YmeI. The frequency of Spi[−] phage was obtained by dividing the titer of Spi[−] phage by the titer of total phage. Burst size was determined by dividing the number of total λ phages in a lysate by the number of total cells in the culture before heat induction.

Protein purifications

BLM^{642–1290} was produced as a fusion with a Mxe–CBD self-cleaving affinity tag in the *E. coli* BL21-Codon-Plus-(DE3)-RIL strain (Stratagene) containing the plasmid pJP71. Cells were grown at 37 °C in 1 l of LB medium supplemented with ampicillin and chloramphenicol at concentrations of 150 μg/ml and 25 μg/ml, respectively. At an A₆₀₀ of 0.3, the cultivation temperature was reduced to 18 °C and protein synthesis was induced by adding isopropyl-β-D-thiogalactopyranoside (IPTG) to a final concentration of 0.2 mM and subsequent incubation for 16 hours. All protein purification steps were carried out at 4 °C. Cells were harvested by centrifugation, suspended in 50 ml of buffer CH (50 mM Tris–HCl (pH 8), 500 mM NaCl, 1 mM EDTA, 10% (v/v) glycerol, 0.1% (v/v) Triton X-100) and disrupted by sonication. The cell extract was clarified by centrifugation in an SS-34 rotor (Sorvall) at 18,000 rpm for 30 minutes. The supernatant was loaded onto a 15 ml chitin column (NEB) at a flow-rate of 12 ml/hour. The column was washed with 20 column volumes of buffer CH. Cleavage of BLM^{642–1290} from the Mxe intein was induced by flushing the column with three column volumes of buffer CH supplemented with 50 mM DTT, with a subsequent incubation overnight at 4 °C. The protein was eluted with buffer CH. Fractions containing BLM^{642–1290} (as judged from SDS-PAGE) were pooled, diluted 2.5 times with 50 mM Tris–HCl (pH 7.5) and loaded onto a 5 ml High-Trap heparin cartridge (Amersham Pharmacia Biotech) equilibrated with buffer HP (50 mM Tris–HCl (pH 7.5), 0.1 mM EDTA, 1 mM DTT, 10% (v/v) glycerol, 200 mM NaCl). The protein was eluted with a linear concentration gradient of NaCl (0.2 M–0.6 M; 50 ml) in buffer HP. Fractions containing BLM^{642–1290} were pooled, diluted three times with 20 mM Tris–HCl (pH 8) and loaded onto a 50 ml CM-Sepharose FF column (Amersham Pharmacia Biotech) equilibrated with buffer CM (20 mM Tris–HCl (pH 8.0), 0.1 mM EDTA, 1 mM DTT, 10% (v/v) glycerol, 150 mM NaCl). The protein was eluted with a linear concentration gradient of NaCl (0.15 M–0.35 M; 500 ml) in buffer CM. Fractions containing BLM^{642–1290} with >95% homogeneity were pooled and concentrated by dialysis against storage buffer (50 mM Tris–HCl (pH 7.5), 200 mM NaCl, 50% (v/v) glycerol, 1 mM DTT). Other BLM variants were produced and purified according to the same protocol. The BLM^{642–1108} protein as well as the R1038A and D1064A mutants of BLM^{642–1290} did not bind to the heparin column under these conditions. However, sufficient purification of these proteins to more than 90% homogeneity could be achieved by combining chromatographies on the chitin and CM-Sepharose FF columns. Protein concentration was determined from absorption at 280 nm using molar extinction coefficients derived from amino acid composition. The full-size BLM protein was kindly provided by Professor Ian D. Hickson from the University of Oxford.

Size-exclusion chromatography

Size-exclusion chromatography of BLM^{642–1290} was performed at room temperature on a Superdex 200 PC3.2/30 column using a SMART system (Amersham Pharmacia Biotech). The column was equilibrated with buffer GF (20 mM Tris–HCl (pH 7.5), 150 mM NaCl, 0.1 mM EDTA, 1 mM DTT). Samples were prepared by dilution of the protein tenfold in GF buffer to a final

concentration of 3 μM . Where required, samples were supplemented with 0.5 μM single-stranded 30mer oligonucleotide: 5'-CCGTCGACTGACCGATATCCTCG GTACCCC-3', 1 mM ATP γS and 5 mM MgCl_2 . Samples were incubated at room temperature for 15 minutes prior to injection of 50 μl aliquots onto the column. The column was run at a flow-rate of 40 $\mu\text{l}/\text{minute}$ and absorbance was monitored at 215 nm, 260 nm and 280 nm. The following size markers were used for calibration of the column: thyroglobulin (669 kDa), ferritin (440 kDa), catalase (232 kDa), aldolase (158 kDa), bovine serum albumin (67 kDa), ovalbumin (43 kDa) and chymotrypsinogen (25 kDa).

DNA helicase assays

DNA helicase activity of BLM and its mutants was measured using either partial DNA duplexes prepared by annealing oligonucleotides to circular M13mp18 ssDNA or using various synthetic duplex substrates. The following oligonucleotides were used for preparation of the partial M13 duplex substrates: 43mer 5'-CTTGCATGCCTGCAGGTCGACTCTAGAGGATCCCC GGGTACCG-3' and 24mer: 5'-CATTAAAGCCAGAATG GAAAGCGC-3'. The oligonucleotides were annealed to M13mp18 ssDNA at molar ratio of 10:1 by heating at 95 $^{\circ}\text{C}$ for five minutes and then cooling to 30 $^{\circ}\text{C}$ at 0.2 deg.C/second. Non-annealed oligonucleotides were removed using a QIAquick PCR purification kit (QIAGEN). Annealed oligonucleotides were radioactively labeled at the 3' end by a filling-in reaction catalyzed by Klenow fragment (NEB) in the presence of [α - ^{32}P]ATP (3000 Ci/mmol; Amersham Pharmacia Biotech) under standard conditions (NEB). The oligonucleotides A₂₀ (50mer), A₀ (30mer), B₁₉ (49mer), B₀ (30mer) and C₁₉ (19mer) were used for the generation of the blunt-ended duplex (A₀ + B₀), 3'-ssDNA-tailed duplex (A₀ + B₁₉), splayed arm (A₂₀ + B₁₉), 5'-ssDNA flap duplex (A₂₀ + B₁₉ + C₁₉) and nicked duplex (A₀ + B₁₉ + C₁₉) have been described.⁵⁴ The oligonucleotides A₂₀ and A₀ were labeled at the 5' end using [γ - ^{32}P]ATP (3000 Ci/mmol; Amersham Pharmacia Biotech) and phage T4 polynucleotide kinase (NEB), and annealed to appropriate complementary strands at a molar ratio of 1:1.25 by incubation at 95 $^{\circ}\text{C}$ for five minutes and then cooling to 30 $^{\circ}\text{C}$ at 0.2 deg.C/second. The 50mer oligonucleotides used to prepare the four-way junction substrate have been described.⁶ One of the oligonucleotides was radio-labeled at the 5' end using [γ - ^{32}P]ATP and T4 polynucleotide kinase. The labeled oligonucleotide was annealed with the other three strands at a molar ratio of 1:4 by incubation at 95 $^{\circ}\text{C}$ for five minutes and then cooling to 30 $^{\circ}\text{C}$ at 0.2 deg.C/second. The radiolabeled four-way junction substrate was separated from other species on a non-denaturing 15% (w/v) polyacrylamide gel (acrylamide to bis-acrylamide, 19:1 (w/w)) run in TBE buffer (90 mM Tris-borate (pH 8.3), 2 mM EDTA) and recovered from the gel by electroelution.

DNA helicase reactions were carried out at 37 $^{\circ}\text{C}$ in buffer H (50 mM Tris-HCl (pH 7.5), 50 mM NaCl, 5 mM MgCl_2 , 50 $\mu\text{g}/\text{ml}$ of bovine serum albumin (BSA), 2 mM ATP, 1 mM DTT). DNA substrates were present at a concentration of 0.5 nM for partial M13 duplexes or 1 nM for synthetic substrates. After two minutes pre-incubation, reactions were started with enzyme and later terminated by addition of 0.5 reaction volume of buffer S (150 mM EDTA, 2% (w/v) SDS, 30% (v/v) glycerol, 0.1% (w/v) bromophenol blue). In protein titration

experiments, reactions were usually carried out in a volume of 10 μl using various quantities of protein (as indicated in the Figure legends) and an incubation time of 30 minutes. To measure the rate of DNA unwinding by BLM⁶⁴²⁻¹²⁹⁰ as a function of ATP concentration, 50 μl time-course reactions were carried out for concentrations of ATP ranging from 10 μM to 2000 μM using 25 bp partial duplex as DNA substrate (0.5 nM) and an enzyme concentration of 20 nM. Reaction aliquots (10 μl) at time-points of 0.5, one, two and three minutes were analyzed.

For all reactions, the displaced radiolabeled oligonucleotide was separated from its annealed form by electrophoresis through a non-denaturing 15% polyacrylamide gel (acrylamide to bis-acrylamide, 37.5:1 (w/w)) run in TBE buffer at 100 V for two hours. Gels were dried and subjected to autoradiography and/or quantified using a PhosphorImager and ImageQuant software (Molecular Dynamics). The $K_{1/2}$ value for ATP (concentration of ATP at which the rate of unwinding was half of the maximal rate) was derived by fitting data by the Michaelis-Menten equation using Prism 2.0 software.

ATPase assays

DNA-dependent ATPase activity was measured using a malachite green assay based on a colorimetric estimation of inorganic phosphate produced by ATP hydrolysis.⁵⁵ Reactions were carried out at 37 $^{\circ}\text{C}$ in buffer H in the presence of saturating amounts of DNA cofactors, including M13mp18 ssDNA, supercoiled pTZ18R plasmid DNA and a 43mer oligonucleotide (see above) as indicated in the Figure and Table legends. Reactions were initiated by adding ATP. Aliquots (5–20 μl) were removed from reactions at various time-points (1, 2, 4, 8, 16, and 32 minutes) and mixed with 20 μl of 0.1 M EDTA to terminate ATP hydrolysis. After appropriate dilution, samples (40 μl) were subjected to malachite green assay in a 96-well microplate as described⁵⁶ along with a series of KH_2PO_4 dilutions ranging from 10 μM to 140 μM that served for calibration. Steady-state kinetic parameters K_M and k_{cat} for ATP were measured at a protein concentration of 20 nM, with the exception of D1064A and R1038A mutants, which were present at concentrations of 40 nM and 100 nM, respectively. The concentration of ATP was varied from 10 μM to 2 mM in these measurements. The K_M and k_{cat} values were derived by fitting data by the Michaelis-Menten equation using Prism 2.0 software.

DNA binding assay

Protein at concentrations ranging from 5 to 640 nM was incubated with 2.5 nM 30mer oligonucleotide (the same as in the gel-filtration experiments) labeled at the 5' end using [γ - ^{32}P]ATP and T4 polynucleotide kinase. Incubations were carried out at room temperature for 20 minutes in buffer B (50 mM Tris-HCl (pH 7.5), 1 mM DTT, 50 mM NaCl, 10% (v/v) glycerol). Samples were subsequently subjected to electrophoresis through a non-denaturing 15% polyacrylamide gel (acrylamide to bis-acrylamide, 37.5:1 (w/w)) run in TBE buffer at 100 V to separate protein-DNA complex from free DNA. Gels were dried and analyzed by a PhosphorImager. The apparent dissociation constant (K_d) was determined as the protein concentration at which 50% of DNA was bound.

Acknowledgements

We thank Hagop Youssoufian for providing us with BLM cDNA, Ian Hickson for supplying the full-size BLM protein, Marcel Hohl for help with preparation of DNA helicase substrates, Ilana Camargo for help with plasmid constructions, Mark Szczelkun and Sergey Korolev for critical reading of the manuscript. This work was supported by the Swiss National Foundation.

Proteins belonging to the highly conserved RecQ helicase family are essential for the maintenance of genomic stability. Here, we describe the biochemical properties of the human RECQ5 β protein. Like BLM and WRN, RECQ5 β is an ATP-dependent 3'–5' DNA helicase that can promote migration of Holliday junctions. However, RECQ5 β required the single-stranded DNA-binding protein RPA in order to mediate the efficient unwinding of oligonucleotide-based substrates. Surprisingly, we found that RECQ5 β possesses an intrinsic DNA strand-annealing activity that is inhibited by RPA. Analysis of deletion variants of RECQ5 β revealed that the DNA helicase activity resides in the conserved N-terminal portion of the protein, whereas strand annealing is mediated by the unique C-terminal domain. Moreover, the strand-annealing activity of RECQ5 β was strongly inhibited by ATP γ S, a poorly hydrolyzable analog of ATP. This effect was alleviated by mutations in the ATP-binding motif of RECQ5 β , indicating that the ATP-bound form of the protein cannot promote strand annealing. This is the first demonstration of a DNA helicase with an intrinsic DNA strand-annealing function residing in a separate domain.

Subject Categories: genome stability & dynamics

Keywords: DNA helicase; genomic instability; Holliday junctions; RecQ; single-strand annealing

Introduction

Helicases are ubiquitous enzymes that use the free energy of nucleotide triphosphate hydrolysis to separate nucleic acid duplexes into the constituent single strands (reviewed in Lohman and Bjornson, 1996; Hall and Matson, 1999; von Hippel and Delagoutte, 2001). They play essential roles in nearly all DNA metabolic processes, including DNA replication, recombination and repair. Helicases often contain additional functional domains or interact with other proteins to mediate complex DNA transactions.

DNA helicases of the RecQ family, named after the 3'–5' DNA helicase RecQ of *Escherichia coli*, unwind a wide variety of potentially recombinogenic DNA structures, including four-way junctions, D-loops and G-quadruplex DNA. RecQ helicases are highly conserved from bacteria to humans, but while prokaryotes and unicellular eukaryotes such as *Saccharomyces cerevisiae* or *Schizosaccharomyces pombe* possess only a single RecQ homolog, multicellular organisms have several (for recent reviews, see Bachrati and Hickson, 2003; Hickson, 2003; Khakhar *et al.*, 2003). In humans, five RecQ homologs have been identified to date: RECQ1, BLM/RECQ2, WRN/RECQ3, RECQ4 and RECQ5. In all organisms, defective RecQ helicase function is associated with genomic instability, which is generally manifested as an increase in the frequency of inappropriate recombination events. Mutations in genes encoding the human RecQ helicases BLM, WRN and RECQ4 give rise to the hereditary disorders Bloom's syndrome, Werner's syndrome and Rothmund–Thomson syndrome, respectively (Bachrati and Hickson, 2003). These diseases are associated with cancer predisposition and variable aspects of premature aging. Although the precise DNA transactions mediated by RecQ helicases remain elusive, the enzymes have been implicated in the processing of aberrant DNA structures arising during DNA replication and repair (Bachrati and Hickson, 2003).

RecQ helicases possess the so-called DEXH helicase and RecQ-Ct (RecQ C-terminal) regions, which form the catalytic core of the enzyme (Bachrati and Hickson, 2003; Bernstein and Keck, 2003). The former domain is homologous to the superfamily 2 helicases, while the latter is unique to the RecQ family. Recent structural studies on the *E. coli* RecQ helicase have shown that the RecQ-Ct region forms two subdomains (Bernstein *et al.*, 2003). The proximal part of this region folds into a platform of four helices containing a Zn²⁺-binding site and the distal part forms a specialized helix–turn–helix motif, called the winged-helix (WH) domain, which serves as a double-stranded DNA (dsDNA)-binding motif in several proteins including the catabolite gene activator protein (Bernstein *et al.*, 2003). Some RecQ helicases also contain the so-called HRDC (Helicase and RNaseD C-terminal) region, which may serve as an auxiliary DNA-binding domain (Liu *et al.*, 1999; Bernstein and Keck, 2003). The eukaryotic members of the RecQ family usually have additional N- and C-terminal domains flanking the RecQ core, which are involved in protein–protein interactions (Bachrati and Hickson, 2003).

Although defects in WRN, BLM and RECQ4 are associated with heritable human disease, such an association has not been demonstrated for RECQ5. Targeted disruption of *RECQ5* in chicken DT40 cells, which have proven to be a valuable model system to study the cellular functions of BLM and WRN, does not result in genomic instability (Imamura *et al.*, 2002; Wang *et al.*, 2003). However, a *RECQ5*^{−/−} *BLM*^{−/−} DT40 double mutant exhibits much higher levels of sister chromatid exchanges (SCEs) than a *BLM*^{−/−} mutant, suggesting that

RECQ5 may serve as backup for BLM (Wang *et al*, 2003). RECQ5 deficiency in *Caenorhabditis elegans* reduces lifespan and increases cellular sensitivity to ionizing radiation (Jeong *et al*, 2003). Together, these findings support the notion that the product of the human RECQ5 gene may be important for the maintenance of genomic stability.

The human RECQ5 protein exists in at least three different isoforms, which result from alternative splicing of the RECQ5 transcript (Shimamoto *et al*, 2000). In addition to the conserved helicase and RecQ-Ct regions, the largest isoform, RECQ5 β , contains a long C-terminal region that displays no homology to the other family members (Figure 7A). Also, in contrast to the other RecQ helicases, RECQ5 β lacks the WH domain. The other two isoforms, RECQ5 α and RECQ5 γ , are almost identical. RECQ5 α terminates inside the RecQ-Ct region, just upstream of the putative Zn²⁺-binding site. RECQ5 γ contains 25 additional amino acids at the C-terminus that are not present in RECQ5 β . The RECQ5 β isoform localizes to the nucleus, whereas the two smaller isoforms are cytoplasmic (Shimamoto *et al*, 2000).

The biochemical functions of these isoforms are unknown. To gain an insight into the potential role of RECQ5 in the maintenance of genomic stability, we have carried out an extensive biochemical analysis of the RECQ5 β protein. We found that RECQ5 β is monomeric and contains two separate functional domains: the N-terminal half of the protein comprising the conserved DEXH and Zn²⁺-binding domains functions as a DNA-dependent ATPase and an ATP-dependent 3'-5' DNA helicase. The unique C-terminal portion possesses an efficient DNA strand-annealing activity. To our knowledge,

this is the first demonstration of a DNA helicase with an intrinsic DNA strand-annealing function residing in a separate domain of the same polypeptide.

Results

DNA-dependent ATPase and 3'-5' DNA helicase activities of RECQ5 β

RECQ5 β was overproduced in *E. coli* as a fusion protein with a self-cleaving affinity tag composed of an intein fragment and a chitin-binding domain (CBD), and purified to more than 95% homogeneity (Figure 1A). To determine the quaternary structure of the RECQ5 β protein in solution, analytical ultracentrifugation experiments were conducted with 0.5 μ M protein. The sedimentation velocity profile of RECQ5 β preparation revealed the presence of a single species with an $S_{20,W}$ value of 5.6. Sedimentation equilibrium measurements yielded an apparent molecular mass of 134 kDa indicating that RECQ5 β exists as a monomer in solution (the predicted value for the monomer is 108.9 kDa). Size-exclusion chromatography on a Superdex 200 column revealed no change in the quaternary structure of the protein upon addition of a 30-mer oligonucleotide and/or ATP γ S-Mg²⁺ (data not shown).

The ATPase activity of RECQ5 β was analyzed in the presence of various DNA molecules, including short oligonucleotides, circular single-stranded DNA (ssDNA), linear dsDNA or supercoiled plasmid DNA. RECQ5 β was found to exhibit robust ATPase activity with both ssDNA and dsDNA, whereas little ATPase activity was observed in the absence of

Figure 1 ATPase and DNA helicase activities of RECQ5 β . (A) A 10% SDS-polyacrylamide gel showing individual RECQ5 β purification steps. RECQ5 β was overproduced in *E. coli* as a fusion with a self-cleaving affinity tag. Lane 1, molecular size marker; lane 2, soluble fraction of whole-cell extract (WCE); lane 3, pooled fractions from the chitin column; lane 4, pooled fractions from the heparin column. (B) ATPase activity of RECQ5 β in the presence of the indicated DNA effectors. Reactions were carried out at 37°C for 30 min and contained 20 nM RECQ5 β , 2 mM ATP and 25 μ g/ml DNA effector. The amount of inorganic phosphate (P_i) released by ATP hydrolysis was determined as described in Materials and methods. sc-dsDNA, supercoiled dsDNA; lin-dsDNA, linear dsDNA. (C) Conventional DNA helicase assay using a 44 bp M13mp18-based duplex radiolabeled at the 3'-end. Reactions were carried out at 37°C for 30 min and contained 0.5 nM DNA, varying concentrations of RECQ5 β and 2 mM ATP (or ATP γ S) as indicated. The reaction products were analyzed by 10% nondenaturing PAGE. Radiolabeled species were visualized by autoradiography. The last lane contains heat-denatured substrate. (D) Helicase polarity assay using a linearized M13mp18-based duplex radiolabeled at the 3'-end. Radiolabeled 3'-ends in this DNA substrate are indicated by asterisks (top panel). Reactions were carried out at 37°C for 30 min and contained 0.5 nM DNA substrate, 40 nM RECQ5 β and 2 mM ATP. The products were analyzed as in (C). Lane 1, substrate incubated without enzyme; lane 2, substrate plus enzyme; lane 3, heat-denatured substrate.

DNA processing by RECQ5 β

PL Garcia *et al*

DNA (Figure 1B). In addition to ATP, RECQ5 β could hydrolyze dATP with a specific activity similar to that observed with ATP (data not shown). We also found that GTP and dGTP could be hydrolyzed in the presence of ssDNA and dsDNA, but the specific activities were approximately 10-fold lower than that observed with ATP (data not shown). No significant hydrolytic activity was observed with other nucleotides.

To determine whether RECQ5 β possesses a DNA helicase activity, we first tested its ability to disrupt an M13mp18-based partial duplex of 44 bp. Using 0.5 nM DNA substrate and increasing amounts of RECQ5 β in the presence of ATP, we observed that RECQ5 β displaced the annealed oligonucleotide in a concentration-dependent manner (Figure 1C). At a protein concentration of approximately 15–20 nM, 50% strand displacement occurred. DNA helicase activity was dependent on ATP hydrolysis, as strand displacement was not observed when ATP was replaced with poorly hydrolyzable ATP analog, ATP γ S (Figure 1C). We found that dATP could substitute for ATP, but failed to observe DNA helicase activity when other nucleotides were used.

To determine the polarity of the RECQ5 β helicase, we employed a linear DNA substrate consisting of M13mp18 ssDNA with short 32 P-labeled (17 and 25 bp) duplex regions at the 5'- and 3'-ends, respectively (Figure 1D, top panel). We found that RECQ5 β could only displace the 17-mer, indicating 3'-5' polarity, which is a general characteristic of the RecQ helicase family (Figure 1D, lower panel).

RECQ5 β requires RPA to unwind oligonucleotide-based partial duplexes

Further analysis of the DNA helicase activity of RECQ5 β revealed that the unwinding of oligonucleotide-based substrates was poor compared with the M13-based partial duplexes. Using a 30-bp forked duplex with single-stranded splayed arms, we observed that the formation of unwound products increased proportionally with protein concentration, peaking at 10 nM with about 20% of the substrate dissociated (Figure 2A). Interestingly, at higher protein concentrations (10–40 nM), the strand displacement activity dropped below the level of spontaneous dissociation of the substrate. At even greater protein concentrations (40–320 nM), the activity again increased gradually with protein concentration (Figure 2A). The inability of RECQ5 β to promote efficient unwinding of an oligonucleotide-based fork structure was surprising since other RecQ helicases such as BLM or WRN exhibit a preference for this substrate (Mohaghegh *et al*, 2001).

To explore the possibility that RECQ5 β requires additional factors to mediate unwinding of oligonucleotide-based substrates, we first examined the effect of the human replication protein A (RPA), an ssDNA-binding protein, on this reaction. RPA has been shown to enhance specifically the unwinding of long DNA duplexes by WRN and BLM (Brosh *et al*, 1999, 2000). We observed that addition of RPA greatly stimulated RECQ5 β -mediated unwinding of the splayed-arm structure in a concentration-dependent manner (Figure 2B). Time-course studies, carried out at 1 nM DNA and 20 nM RECQ5 β , showed that in the presence of 24 nM RPA (trimer) the unwinding reaction was completed in <16 min (Figure 2C). The *E. coli* ssDNA-binding (SSB) protein (120 nM) could partially substitute for RPA, but the efficiency of unwinding was reduced

Figure 2 Stimulation of RECQ5 β helicase activity on oligonucleotide-based partial duplexes by ssDNA-binding proteins. (A) Unwinding of 1 nM 30-bp forked duplex, 32 P-end labeled in the 5'-ssDNA arm, by RECQ5 β at concentrations ranging from 0 to 320 nM. Reactions were incubated at 37°C for 20 min, and the products were analyzed by 10% nondenaturing PAGE. Radiolabeled species were visualized by autoradiography. (B) Unwinding of 1 nM 30-bp forked duplex by 20 nM RECQ5 β in the presence of the indicated concentrations of RPA. Reactions were carried out and analyzed as in (A). (C) Kinetics of unwinding of 1 nM 30-bp forked duplex by 20 nM RECQ5 β in the presence of 24 nM RPA, 120 nM *E. coli* SSB or without any ssDNA-binding protein. The percentage strand displacement was estimated as described in Materials and methods.

(Figure 2C). These results indicate that the stimulatory effect of RPA may involve specific interactions between RPA and RECQ5 β , in addition to its effect in binding the ssDNA products.

RECQ5 β promotes Holliday junction branch migration

The BLM and WRN proteins interact with Holliday junctions (HJs) and promote their migration (Constantinou *et al*, 2000; Karow *et al*, 2000). To determine whether RECQ5 β could catalyze similar reactions, we analyzed its activity with the synthetic HJ substrate X26 that contains a 26-bp core of homologous sequences flanked by heterologous arm sequences. In the presence of ATP, we observed concentration-dependent branch migration that generated splayed-arm products (Figure 3A, lanes 2–6). Branch migration was stimulated by the presence of RPA (Figure 3A, lanes 8–11, and Figure 3B).

In these reactions, comparatively few three-strand junctions or single-stranded products were observed, indicating that the primary RECQ5 β -mediated reaction involved recognition of the HJ followed by its movement and dissociation into splayed-arm products. This proposal was supported by the analysis of RECQ5 β -mediated branch migration reactions in which the DNA substrate was preincubated with *E. coli* RuvA, a protein known to bind HJs with high specificity.

Figure 3 Branch migration of HJs by RECQ5 β . (A) RECQ5 β -mediated branch migration in the presence or absence of RPA. Reactions contained 0.5 nM synthetic junction X26, and the indicated amounts of RECQ5 β protein in the presence or absence of 20 nM RPA. Reactions were carried out at 37°C for 15 min, and the DNA products were analyzed by neutral PAGE. Lane 1, control reaction with *E. coli* RuvA (25 nM) and RuvB (50 nM). (B) Quantification of the data shown in (A). The relative concentration of the dissociated products is expressed as percentage of total DNA. The dissociated products include three-way junctions, splayed arms (the products of branch migration) and ssDNA. Background levels of dissociated species have been subtracted. (C) Inhibition of RECQ5 β branch migration activity by the *E. coli* HJ-binding protein RuvA. RuvA was preincubated with the junction in reaction buffer for 1 min prior to the addition of the RECQ5 β protein. Incubation was then continued, and the products were assayed as described in (A).

We found that the presence of 40 nM RuvA imposed a complete block to branch migration mediated by 25 nM RECQ5 β (Figure 3C).

The ability of RPA to stimulate branch migration could be a consequence of its ability to bind the single-stranded arms of reaction products thereby (i) stimulating the forward reaction or (ii) blocking a reverse reaction in which the splayed-arm

Figure 4 RPA stimulates RECQ5 β -mediated branch migration by inhibiting DNA reannealing. (A) Time course of branch migration of 0.5 nM X26 mediated by 50 nM RECQ5 β either in the presence or absence of 20 nM RPA. Reactions were carried out at 37°C, and the DNA products were analyzed by neutral PAGE. (B) Quantification of products (three-way junction, splayed-arm branch migration products and single strands) formed during the reactions shown in (A). The relative concentration of the products is expressed as percentage of total dissociated products. (C) Time course of branch migration of 0.5 nM X26 mediated by 50 nM RECQ5 β in the presence or absence of excess *E. coli* SSB protein (1 μ M). Reactions were carried out and analyzed as in (A).

structures reannealed to reform the HJ structure. To distinguish between these possibilities, time-course studies were carried out in the presence and absence of RPA. Without RPA, formation of the splayed-arm branch migration products was greater after 5 min than at later time points (Figure 4A, lanes 3–6, and Figure 4B). This surprising result contrasts with data obtained with reactions carried out in the presence of RPA, in which splayed-arm products accumulated in a time-dependent manner (Figure 4A, lanes 7–11, and Figure 4B). As observed in the helicase assays described earlier, SSB could only partially substitute for RPA (Figure 4C). Taken together, these results indicate that RPA plays a specific role in the branch migration reaction, by specifically inhibiting the reannealing of the splayed-arm products. RPA stimulation therefore involves inhibition of annealing, rather than stimulation of branch migration.

RECQ5 β possesses DNA strand-annealing activity

The finding that the RECQ5 β -mediated dissociation of four-way junctions to splayed-arm products was followed by a

DNA processing by RECQ5 β PL García *et al*

slow reannealing reaction (Figure 4A) encouraged us to test whether RECQ5 β itself possesses the ability to promote the annealing of complementary single strands. We therefore incubated two partially complementary oligonucleotides (those used to make the splayed-arm helicase substrate) with increasing amounts of RECQ5 β in the absence of ATP, and subsequently analyzed the reaction products by 10% nondenaturing polyacrylamide gel electrophoresis (PAGE). We found that RECQ5 β promoted an efficient annealing reaction (Figure 5). Using 1 nM ssDNA, we found that annealing was dependent on protein concentration, with the reaction being most efficient at around 40 nM RECQ5 β (Figure 5A). A large excess of RECQ5 β over DNA slightly inhibited single-strand annealing, possibly as a consequence of protein aggregation (Figure 5A). Time-course experiments conducted at the optimal concentration of RECQ5 β (40 nM) revealed that the RECQ5 β -promoted annealing reaction was rapid, with 50% of the single-stranded substrate being converted into the double-stranded product within 2 min (Figure 5B). In contrast, spontaneous DNA annealing was slow, with only 15% of the substrate being converted to dsDNA after 32 min (Figure 5B). These findings provide an explanation for the apparent poor helicase activity displayed by RECQ5 β on oligonucleotide-based substrates.

RECQ5 β was also tested for its ability to promote the annealing of a short oligonucleotide to a target sequence in M13mp18 ssDNA, which contains a large excess of heterologous sequences. In this experiment, a 32 P-end-labeled 43-mer oligonucleotide (also used in the helicase assays shown in Figure 1C) was preincubated with RECQ5 β followed by the addition of M13mp18 ssDNA. RECQ5 β promoted the annealing of the oligonucleotide to the M13mp18 ssDNA (Figure 5C). However, the yield of the annealed product in this reaction was significantly lower than that of the RECQ5 β -promoted annealing of complementary oligonucleotides (compare Figure 5A and C). This negative effect of heterologous DNA sequences on RECQ5 β -mediated strand annealing correlates with our earlier studies in which it was shown that RECQ5 β efficiently unwinds M13mp18-based partial duplexes (Figure 1C).

To gain further insight into the mechanism of RECQ5 β -mediated DNA strand annealing, we investigated whether coating of the oligonucleotides with RPA would affect the annealing reaction. Assuming that the size of the DNA-binding site for RPA is about 30 nucleotides (nt) (Kim *et al*, 1992), we anticipated that the two partially complementary oligonucleotides (with lengths of 50 and 49 nt) would each be occupied by 1–2 RPA heterotrimers. The oligonucleotides (1 nM) were first preincubated with RPA at a concentration ranging from 0 to 24 nM for 2 min. After this DNA-binding reaction, RECQ5 β was added to a final concentration of 40 nM and incubation was continued for 20 min. This protein titration experiment revealed that the presence of RPA at concentrations above 3 nM completely inhibited the DNA strand-annealing activity of RECQ5 β (Figure 5D). This result correlates with the observation that RPA enhances the DNA helicase activity of RECQ5 β on the oligonucleotide-based substrates (Figure 2C) and also blocks the reassociation of splayed-arm products resulting from RECQ5 β -promoted HJ branch migration on the X26 structure (Figure 4A and B).

Figure 5 RECQ5 β promotes DNA strand annealing. **(A)** Formation of 30-bp forked duplex in the presence of varying concentrations of RECQ5 β . The A20 and B19 complementary oligonucleotides (1 nM), of which A20 was radiolabeled at its 5'-end, were incubated with the indicated concentrations of RECQ5 β for 20 min at 37°C. The reaction products were separated by 10% nondenaturing PAGE and visualized by autoradiography. **(B)** Kinetics of RECQ5 β -mediated and spontaneous formation of 30-bp forked duplex. Reactions were carried out at 37°C. The component strands A20 and B19 were present at a concentration of 1 nM and RECQ5 β was at a concentration of 40 nM. Reactions were initiated by the addition of unlabeled B19 oligonucleotide. The relative concentration of the strand-annealing product was determined as described in Materials and methods. **(C)** Annealing of 1 nM 32 P-end-labeled Hel-1 oligonucleotide (43-mer) to 2 nM M13mp18 ssDNA in the absence or presence of 100 nM RECQ5 β . Reactions were carried out at 37°C for 20 min and analyzed as in (A). RECQ5 β was preincubated with Hel-1 for 2 min at room temperature prior to the addition of M13mp18 ssDNA. Lane 1, Hel-1 alone; lane 2, Hel-1 and M13mp18 ssDNA; lane 3, Hel-1, M13mp18 ssDNA and RECQ5 β . **(D)** Effect of RPA on RECQ5 β -mediated DNA strand annealing. The complementary oligonucleotides A20 and B19 (1 nM), of which A20 was radiolabeled, were incubated with or without RPA for 5 min at room temperature. RECQ5 β was added to a final concentration of 40 nM and incubation was continued at 37°C for 20 min. The reaction products were analyzed as in (A).

ATP binding to the helicase domain of RECQ5 β suppresses strand annealing

We next sought to examine the effect of ATP on the strand-annealing activity of RECQ5 β . Since ATP can be hydrolyzed by RECQ5 β under the conditions of the strand-annealing assay, we also employed the poorly hydrolyzable analog of ATP, ATP γ S, in order to trap RECQ5 β in its ATP-bound form. Using the two partially complementary oligonucleotides, we found that the presence of ATP or ADP had little or no effect on the RECQ5 β -mediated strand-annealing reaction (Figure 6A). In contrast, ATP γ S dramatically inhibited the efficient strand-annealing activity of RECQ5 β (Figure 6A). These data imply that the observed inhibitory effect is the consequence of ATP binding rather than hydrolysis.

Figure 6 The ATP-bound form of RECQ5 β does not promote DNA strand annealing. (A) Effect of ATP, ATP γ S and ADP on RECQ5 β -promoted annealing of the A20 and B19 oligonucleotides. Reactions were carried out at 37°C for 20 min and contained 40 nM RECQ5 β , 1 nM DNAs and 2 mM nucleotides as indicated. The reaction products were analyzed by 10% nondenaturing PAGE. Radiolabeled species were visualized by autoradiography. (B) Comparative ATPase assay for wild-type, Q34A, K58R and Q34AK58R RECQ5 β . ATPase reactions were carried out essentially as described in Figure 1B using A20 oligonucleotide as a DNA effector. (C) Comparative ATP-binding assay for wild-type, Q34A, K58R and Q34AK58R RECQ5 β . ATP binding was measured using the ATP photo-crosslinking assay described in Materials and methods. The material was resolved on a 10% SDS-polyacrylamide gel, stained with Coomassie brilliant blue (bottom panel) and subjected to autoradiography (top panel). The asterisks indicate the position of the RECQ5 β protein. (D) Effect of ATP γ S on DNA strand-annealing activities of the wild-type, Q34A, K58R and Q34AK58R RECQ5 β . Reaction conditions and analyses were as described in (A).

We next used a mutational approach to prove that the inhibitory effect of ATP γ S on RECQ5 β -mediated strand-annealing was due to its binding to the ATP-binding site of the RECQ5 β helicase domain. In the crystal structure of the complex of the *E. coli* RecQ catalytic core with ATP γ S and Mn²⁺, the adenine moiety forms hydrogen bonds with Gln-30 of motif 0 while the triphosphate is bound to Lys-53 of motif 1 (Bernstein *et al*, 2003). We therefore generated mutants in the corresponding residues of RECQ5 β , Gln-34 and Lys-58, by replacing them with alanine and arginine, respectively. Both single and double mutants were generated, purified essentially as the wild-type enzyme and tested for their ability to bind and hydrolyze ATP. We found that the Q34A mutant retained partial ATPase activity (about 50% of wild type), whereas the K58A mutant and the double mutant failed to show any significant ATPase activity (Figure 6B). Using a UV crosslinking assay with [γ -³²P]ATP, we found that all three mutants exhibited reduced ATP binding relative to the wild-type enzyme (Figure 6C).

The partially complementary oligonucleotides were then used to assess the effect of ATP γ S on the strand-annealing activity of the mutant RECQ5 β proteins. We found that, in the absence of ATP γ S, all mutant proteins promoted DNA annealing, although the activities of the K58R mutant and the double mutant were slightly reduced compared to that of the wild-type enzyme (Figure 6D). However, in contrast to the dramatic inhibitory effect seen with the wild-type enzyme, ATP γ S only partially inhibited the strand-annealing activity of the Q34A mutant and had no effect on the strand-annealing activities of the K58R and Q34AK58R mutants (Figure 6D). These results correlate nicely with the observed ATPase activities of these proteins (Figure 6B), and show that the ATP-bound form of RECQ5 β does not possess the ability to promote the reannealing of two complementary DNA strands.

DNA strand-annealing activity resides in the C-terminal region of RECQ5 β

To define the region of RECQ5 β responsible for the observed strand-annealing activity, the RECQ5¹⁻⁴⁷⁵ and RECQ5⁴¹¹⁻⁹⁹¹ deletion variants (Figure 7A) were tested for their ability to promote this reaction. The former mutant consists of the conserved portion of RECQ5 β including the DExH and the Zn²⁺-binding domains while the latter includes the unique C-terminal half of RECQ5 β . In these reactions, we used two fully complementary 50-mer oligonucleotides. We found that the annealing activity promoted by RECQ5¹⁻⁴⁷⁵ was only slightly greater than that observed in the absence of added protein and 30-fold lower than that of the wild-type enzyme (Figure 7B). In contrast, RECQ5⁴¹¹⁻⁹⁹¹ displayed a significant strand-annealing activity although the rate of this reaction was reduced (four-fold) with respect to the wild-type enzyme (Figure 7B). From these data, we suggest that the observed DNA strand-annealing activity resides in the unique C-terminal part of the RECQ5 β polypeptide, although it is evident that the helicase domain increases this activity possibly by enhancing the affinity of the enzyme for ssDNA.

Because RECQ5¹⁻⁴⁷⁵ does not display a significant DNA strand-annealing activity and contains the entire helicase catalytic core, we anticipated that it would unwind oligonucleotide substrates more efficiently than the full-size protein. To address this question, we compared the helicase activities of RECQ5 β and RECQ5¹⁻⁴⁷⁵ on the 30-bp splayed-arm sub-

DNA processing by RECQ5 β PL García *et al*

Figure 7 The DNA strand-annealing activity resides in the unique C-terminal portion of the RECQ5 β polypeptide. **(A)** Schematic diagrams indicating RECQ5 β and the variant proteins used in this study. The DEXH helicase and RecQ-Ct domains conserved among the members of the RecQ family are shown as dark- and light-gray boxes, respectively. The location of the putative Zn²⁺-binding site within the RecQ-Ct region is indicated as a checkered box. The remaining portion represents the region that is not conserved in the RecQ family. The numbers on the right refer to the primary amino-acid sequence of RECQ5 β . **(B)** Kinetics of annealing of 1 nM 50-mer complementary oligonucleotides A20 and B20 (A20 was radioactively labeled at its 5'-end) in the presence of 20 nM RECQ5 β , 20 nM RECQ5 β 1-475, 20 nM RECQ5 β 411-991 or without protein. Reactions were carried at 37°C. The relative concentration of the strand-annealing product was determined as described in Materials and methods. **(C)** Unwinding of a 30-bp forked duplex by RECQ5 β and RECQ5 β 1-475 as a function of enzyme concentration. Reactions were carried out at 37°C for 20 min and contained 1 nM DNA, 2 mM ATP and varying amounts of enzyme. The percentage of unwound DNA was determined as described in Materials and methods.

strate at a wide range of protein concentrations (0–320 nM). We found that RECQ5 β 1-475 exhibited a significantly greater DNA helicase activity than the wild-type enzyme at protein concentrations > 20 nM, at which RECQ5 β displayed efficient strand-annealing activity (compare Figures 5A and 7C). As mentioned above, the helicase activity of RECQ5 β displayed a biphasic dependence on protein concentration. In contrast, the helicase activity of RECQ5 β 1-475 gradually increased within the protein concentration range used (Figure 7C). The increase in helicase activity of RECQ5 β at enzyme concentrations above 40 nM presumably reflects an inhibitory effect of ATP on the RECQ5 β -mediated reannealing reaction, which we have observed to become more pronounced at elevated protein concentrations (data not shown).

We conclude that RECQ5 β contains two separate functional domains: a DNA helicase domain and a DNA strand-annealing domain.

Discussion

In this work, we have defined the biochemical characteristics of the human RECQ5 β protein, a member of the RecQ family of DNA helicases. Our work revealed that RECQ5 β functions as an ssDNA/dsDNA-dependent ATPase and an ATP-dependent 3'-5' DNA helicase with the ability to promote branch migration of HJs. These characteristics are shared by other members of the RecQ helicase family (Bachrati and Hickson, 2003). However, in contrast to BLM and WRN that form oligomeric structures (Karow *et al*, 1999; Xue *et al*, 2002), the RECQ5 β helicase exists as a monomer both in free and DNA/ATP-bound forms. Most importantly, our analyses revealed that RECQ5 β exhibits an efficient DNA strand-annealing activity, residing in the unique C-terminal half of the protein. Such a feature has not been seen for any DNA helicase characterized so far.

The observed inhibition of RECQ5 β -mediated DNA strand annealing by RPA indicates that the annealing mechanism is likely to be distinct from the mode of action of classical single-strand-annealing proteins such as RAD52, which involves a cooperative interaction with the complex of the cognate ssDNA-binding protein and ssDNA (Sugiyama *et al*, 1998). Moreover, classical strand-annealing proteins are known to form oligomeric ring structures (Van Dyck *et al*, 1998; Passy *et al*, 1999; Stasiak *et al*, 2000), whereas RECQ5 β protein is monomeric. Structural analyses of the mechanism of RAD52-mediated strand annealing revealed that multiple RAD52 rings appear to be the active catalytic species in the reaction, with ssDNA bound around each ring with the bases exposed on the surface of the protein (Van Dyck *et al*, 2001; Singleton *et al*, 2002).

The strand-annealing mechanism exhibited by RECQ5 β may be more closely related to that of MRE11, which is also strongly inhibited by RPA (de Jager *et al*, 2001). MRE11 is thought to promote DNA annealing by bridging two complementary DNA segments such that their close proximity results in base pairing and duplex DNA formation. Consistent with this mode of annealing, RECQ5 β -mediated annealing of complementary DNA strands was dramatically reduced by the presence of a large excess of heterologous DNA sequence, as found by measuring the annealing of a short oligonucleotide to the complementary region in M13mp18 ssDNA.

We also found that the DNA strand-annealing activity of RECQ5 β was inhibited by the binding of ATP γ S to the helicase domain of the enzyme. Since helicases are known to translocate along DNA in a reaction driven by ATP binding and hydrolysis, we suggest that ATP γ S binding may lead to the formation of an intermediate DNA-protein complex that is incapable of DNA translocation. Alternatively, the binding of ATP γ S may induce an allosteric change in RECQ5 β leading to inactivation of the putative DNA strand-annealing domain. The fact that ATP did not produce a significant inhibitory effect is presumably due to its hydrolysis by the ssDNA-enzyme complex that drives protein translocation and release from the ssDNA template, allowing the strand-annealing domain to mediate duplex formation. These findings are

consistent with a model in which the helicase and the strand-annealing domains of RECQ5 β act in a coordinated fashion.

In the case of oligonucleotide-based partial duplexes as well as four-way junctions, the strand-annealing activity of RECQ5 β dominated over its helicase activity, unless the annealing reaction was blocked by coating of the displaced DNA strands with RPA. In contrast, RECQ5 β displayed an efficient DNA helicase activity with the M13-based partial duplexes. We suggest that the M13-ssDNA substrate may trap the strand-annealing moiety of RECQ5 β , thus effectively disabling the annealing activity. Under these conditions, RECQ5 β could act as a DNA helicase. With oligonucleotide substrates, the strand-annealing domain is free to mediate DNA reannealing during, or immediately after, the strand displacement reaction.

Previous biochemical analysis of the large RECQ5 isoform of *Drosophila melanogaster* (DmRECQ5/QE) did not reveal the presence of an intrinsic DNA strand-annealing activity (Kawasaki *et al*, 2002). However, it should be noted that the helicase activity of DmRECQ5/QE was tested solely on M13-based substrates. In addition, the C-terminal half of human RECQ5 β that is responsible for the observed strand-annealing activity shows extensive amino-acid sequence homology to the corresponding part of the DmRECQ5/QE polypeptide (Shimamoto *et al*, 2000). Therefore, the existence of this activity in the *Drosophila* protein cannot be excluded.

At the present time, the biological significance of our findings cannot be readily assessed because of the lack of information on the phenotypic consequences of RECQ5 deficiency in human cells. It is known that targeted inactivation of the chicken RECQ5 homolog results in a dramatic increase in the frequency of SCEs, albeit solely in a *BLM*^{-/-} background (Wang *et al*, 2003). BLM and DNA topoisomerase III α (TOPOIII α) have been shown to affect the dissolution of double HJ recombination intermediates using a strand-passage mechanism. This reaction yields only non-crossover products, explaining the observed high levels of SCEs in BLM-deficient cells (Wu and Hickson, 2003). Our observation that the human RECQ5 β protein can promote HJ branch migration, an essential step in HJ or replication intermediate processing, in combination with the finding that RECQ5 β co-immunoprecipitates with TOPOIII α and TOPOIII β from human cell extracts (Shimamoto *et al*, 2000) is consistent with a model in which RECQ5 β serves as a backup for BLM. However, we show here that RECQ5 β has substantially different biochemical properties compared to those of BLM. It is therefore plausible that it has alternative and possibly more specialized cellular roles.

The biochemical properties of RECQ5 β led us to suggest that the protein may be involved in a DNA repair pathway that requires the coordinated action of DNA helicase and DNA strand-annealing activities. Depletion of the RECQ5 homolog in *C. elegans* results in hypersensitivity to γ -radiation (Jeong *et al*, 2003), indicating that RECQ5 β may play a role in the repair of radiation-induced lesions such as DNA double-strand breaks, or may be active at stalled replication forks that arise through radiation damage. One attractive possibility is that the DNA helicase and reannealing activities of RECQ5 β are coordinated to mediate fork regression, such that the helicase promotes movement of the branch point while the annealing activity facilitates base pairing of the newly synthesized strands during the regression reaction. In

agreement with this hypothesis, the small *Drosophila* RECQ5 isoform was found to unwind preferentially the 'lagging-strand arm' in a synthetic DNA molecule resembling a stalled replication fork (Ozsoy *et al*, 2003). Further analysis of the precise cellular roles of RECQ5 β will shed light on the functions of the RecQ helicases in maintenance of genomic stability.

Materials and methods

Plasmid construction

The PP1045 cDNA including the RECQ5 β codons 411–991 (GenBank accession no. AF193041, kindly provided by Dr Gu) and the RECQ5 γ cDNA (kindly provided by Dr J Sekelsky) were used as PCR templates to reconstruct the full-size RECQ5 β coding region. In the first step, the 5'- and 3'-halves of the RECQ5 β coding region overlapping in the codons 403–417 were amplified and the resulting DNA fragments were fused in a second round of PCR amplification to yield the entire RECQ5 β coding region. The coding region of RECQ5 β was then inserted between the *Nde*I and *Sap*I sites of the plasmid pTXB1 (NEB) to construct a translational fusion between RECQ5 β and a self-cleaving affinity tag composed of an Mxe intein fragment and the CBD. The resulting plasmid was named pPG10. An additional methionine codon was placed between RECQ5 β and the affinity tag according to the manufacturer's instructions. The plasmids pPG16 and pPG19 encoding the deletion variants of RECQ5 β (RECQ5^{411–991} and RECQ5^{1–475}, respectively) were constructed in the same way as pPG10. Site-directed mutagenesis of the ATP-binding motifs of RECQ5 β was performed using a QuickChangeTM site-directed mutagenesis kit (Stratagene) essentially according to the manufacturer's protocol with pPG10 as template.

Protein purifications and analysis

The RECQ5 β protein and its variants were produced as C-terminal fusions with the self-cleaving Mxe-CBD affinity tag in the *E. coli* BL21-CodonPlus-(DE3)-RIL cells (Stratagene) and purified essentially as previously described for the production and purification of the BLM^{642–1290} fragment (Janscak *et al*, 2003). *E. coli* RuvA and RuvB were purified as described (Eggleston *et al*, 1997) and *E. coli* SSB was purchased from USB. Human RPA protein was prepared essentially as described, but the purification procedure also included chromatography on an ssDNA-cellulose column (Henricksen *et al*, 1994). Concentrations of proteins are expressed in moles of monomer except for RPA, which is expressed in moles of trimeric complex.

Gel filtration chromatography on a Superdex 200 PC3.2/30 column was performed using an AKTA system (Amersham Pharmacia Biotech) under the conditions described previously (Janscak *et al*, 2003). Sedimentation velocity and sedimentation equilibrium runs were carried out in a buffer containing 20 mM Tris-HCl (pH 7.5), 75 mM NaCl, 0.1 mM EDTA and 1 mM DTT as described previously (Janscak *et al*, 2001).

DNA substrates

All oligonucleotides used in the helicase and strand-annealing assays were purchased from Microsynth (Switzerland) and purified by PAGE. The oligonucleotides A20 (50-mer) and B19 (49-mer) are described elsewhere (Hohl *et al*, 2003). The 43-mer Hel-1 (5'-CTTGATGCCTGCAGGTCGACTCTAGAGGATCCCGGTACCG-3') is complementary to the M13mp18 viral strand. The 50-mer B20 (5'-GAGGTCACCTCCAGTGAATTCGAGCTCGAGTGTCTAGGTCGTGACTT TGA-3') is the complement of A20. The M13mp18-based partial-duplex substrate for conventional helicase assays was prepared by annealing the Hel-1 43-mer to circular M13mp18 ssDNA (NEB) and by extension of this molecule by 1 nt using the Klenow fragment (NEB) and [α -³²P]dATP (Amersham Pharmacia Biotech) as described previously (Janscak *et al*, 2003). The substrate for the helicase polarity assay was prepared by cutting the 43-bp M13mp18/Hel-1 partial duplex with *Acl*I to produce a linear ssDNA molecule with short duplex regions at both ends. All available 3'-ends in this molecule were radioactively labeled using the Klenow fragment, [α -³²P]dATP and [α -³²P]dCTP. For oligonucleotide-based helicase substrates, one of the oligonucleotides was labeled at the

DNA processing by RECQ5 β

PL García *et al*

5'-end using T4 polynucleotide kinase (NEB) and [γ - 32 P]ATP, and annealed to the appropriate complementary strand as described (Janscak *et al*, 2003). The synthetic HJ X26, which contains a 26 base pair region of homology flanked by heterologous arms, was made by annealing four oligonucleotides as described (Constantinou *et al*, 2001).

ATPase assays

ATPase activity was determined by colorimetric estimation of the concentration of inorganic phosphate released by ATP hydrolysis using the malachite green assay in a 96-well microplate setup (Chan *et al*, 1986; Janscak *et al*, 1996). Reactions were carried out at 37°C in a buffer containing 50 mM Tris-HCl (pH 7.5), 50 mM NaCl, 2 mM MgCl₂, 1 mM DTT and 50 μ g/ml BSA. Reaction mixtures (typically 20 μ l) contained 20 nM wild-type or mutant RECQ5 β in the presence or absence of saturating concentrations of DNA effectors (25 μ g/ml). Supercoiled pGEM-13Zf(+) DNA (Stratagene), *Nde*I-linearized pGEM-13Zf(+) DNA, single-stranded pGEM-13Zf(+) DNA, and 45- and 21-mer oligonucleotides were used as DNA effectors. Reactions were usually initiated by adding ATP to a final concentration of 2 mM and terminated after 30 min by adding one reaction volume of 0.1 M EDTA (pH 8.0).

Helicase assays

Helicase reactions were carried out at 37°C in buffer HA (20 mM Tris-acetate, pH 7.9, 50 mM KOAc, 10 mM Mg(OAc)₂, 1 mM DTT, 50 μ g/ml BSA). Reaction mixtures (10 μ l) contained either 0.5 nM M13mp18-based or 1 nM oligonucleotide-based partial duplexes, 2 mM ATP and indicated concentrations of RECQ5 β (or its mutants). Where required, RPA or SSB was added at indicated concentrations. Reactions were started with enzyme and terminated typically after 20 min by adding 0.5 reaction volumes of solution S (150 mM EDTA, 2% (w/v) SDS, 30% (v/v) glycerol, 0.1% (w/v) bromophenol blue). In time-course experiments, the reaction volume was 50 μ l, and 5 μ l aliquots were removed at 0.5, 1, 2, 4, 8, 16 and 32 min. The reaction mixtures were resolved using a 10% (w/v) polyacrylamide gel (acrylamide to bis-acrylamide ratios 19:1 for oligonucleotide substrates and 37.5:1 for M13mp18-based substrates) run in TBE buffer (90 mM Tris-borate (pH 8.3), 2 mM EDTA) at 100 V and room temperature. Radiolabeled DNA species were visualized by autoradiography and quantified using a Molecular Dynamics Typhoon 9400 scanner with associated IMAGEQUANT software. The relative concentration of displaced products was expressed as percentage of total DNA.

Branch migration assay

Reactions were carried out at 37°C in a buffer containing 50 mM Tris-HCl (pH 8.0), 2 mM MgCl₂, 2 mM ATP, 1 mM DTT and 100 μ g/ml

BSA. Reaction mixtures (10 μ l) contained 0.5 nM 5'- 32 P-labeled synthetic HJ DNA (X26) and indicated amounts of RECQ5 β . RPA (20 nM) or SSB (1 μ M) was added as indicated. For the inhibition experiment, RuvA was preincubated with the HJ in reaction buffer for 1 min at room temperature before the addition of RECQ5 β protein. The DNA products were deproteinized and electrophoresed through 10% neutral polyacrylamide gels. Control reactions with RuvAB (25 nM RuvA, 50 nM RuvB) were carried out in a buffer containing 20 mM Tris-acetate (pH 7.5), 15 mM Mg(OAc)₂, 2 mM ATP, 1 mM DTT and 100 μ g/ml BSA.

DNA strand-annealing assays

The DNA strand-annealing activity of RECQ5 β was measured using complementary synthetic oligonucleotides (each at a concentration of 1 nM) of which one was labeled at the 5'-end using [γ - 32 P]ATP and T4 polynucleotide kinase. Annealing of a 32 P-labeled oligonucleotide (1 nM) to M13mp18 ssDNA (2 nM) was also measured. Annealing reactions (typically 10 μ l) were carried out at 37°C in buffer HA and contained the indicated amounts of RECQ5 β (or its mutants). Where required, RPA (0.38–24 nM), ATP (2 mM), ATP γ S (2 mM) and ADP (2 mM) were added. Reactions were usually initiated by adding the unlabeled DNA strand and were incubated for 20 min. In time-course experiments, 50 μ l reactions were initiated and 5 μ l aliquots were removed at 0.5, 1, 2, 4, 8, 16 and 32 min. Reactions were analyzed essentially as the helicase reactions (see above).

ATP photo-crosslinking

Purified protein (1 μ g) was incubated in a volume of 10 μ l of buffer HA with 25 μ M ATP and 2 μ Ci of [γ - 32 P]ATP (3000 Ci/mmol; Amersham Pharmacia Biotech) for 5 min at 37°C. Reactions were spotted onto Parafilm, placed on ice and irradiated for 5 min using a UV-Stratalinker 1800 lamp (Stratagene). The covalent protein-ATP complex was separated from free ATP by electrophoresis in a 10% SDS-polyacrylamide gel. Radiolabeled species were visualized by autoradiography. The gel was subsequently stained with Coomassie brilliant blue to determine the position of the protein.

ABSTRACT

Bloom (BLM) and Werner (WRN) syndrome proteins are members of the RecQ family of SF2 DNA helicases. In this paper, we show that restricting the rotational DNA backbone flexibility, by introducing vinylphosphonate internucleotide linkages in the translocating DNA strand, inhibits efficient duplex unwinding by these enzymes. The human single-stranded DNA binding protein replication protein A (RPA) fully restores the unwinding activity of BLM and WRN on vinylphosphonate-containing substrates while the heterologous single-stranded DNA binding protein from *Escherichia coli* (SSB) restores the activity only partially. Both RPA and SSB fail to restore the unwinding activity of the SF1 PcrA helicase on modified substrates, implying specific interactions of RPA with the BLM and WRN helicases. Our data highlight subtle differences between SF1 and SF2 helicases and suggest that although RecQ helicases belong to the SF2 family, they are mechanistically more similar to the SF1 PcrA helicase than to other SF2 helicases that are not affected by vinylphosphonate modifications.

INTRODUCTION

Helicases are motor proteins that use free energy from nucleotide triphosphate hydrolysis for unwinding of nucleic acid duplexes (1–4). Helicases can be classified as one of two types: those that translocate along a nucleic acid strand in a 3' to 5' direction and those that operate with the opposite polarity. Based on amino acid sequence homology, helicases have been grouped into five superfamilies (SF1–5) (5). Most of the known 3'–5' DNA helicases are members of SF1 or SF2. These two superfamilies have similar sets of conserved motifs that are responsible for coupling of ATP hydrolysis to DNA translocation and unwinding. The SF1 and SF2 proteins are mostly monomeric, but the oligomeric state of the functional

form of these enzymes remains to be clarified, since both monomeric and oligomeric models have been proposed (6–11). Out of various models proposed for DNA unwinding by helicases, the so-called inchworm model (12) seems to be the most plausible for the SF1 and SF2 enzymes (6,13). This model is reminiscent of a 'snowplow' which is pushed or pulled along the nucleic acid duplex mechanically forcing the duplex to dissociate into the constituent strands. Extensive structural and biochemical studies on the SF1 helicase PcrA suggested the mechanism of how the free energy of ATP hydrolysis is converted to the mechanical force required for the motion. The ATP binding site of the enzyme is located in the cleft between two RecA-like domains, with residues from seven helicase signature motifs mediating protein–nucleotide interactions (6). DNA is bound along a groove on the top of the RecA-like domain and the cleft closes and opens in response to ATP binding and hydrolysis, suggesting a mechanism for DNA translocation (6). A similar situation exists also in the other SF1 and SF2 helicases which have been analyzed to atomic resolution (14–16). However, it appears that there is a mechanistic distinction between the SF1 and SF2 helicases in the nature of contacts between the translocating motor and the DNA substrate (4). Structural studies of the SF1 helicases PcrA and Rep revealed that they bind to the substrate via hydrophobic interactions with the bases and thus translocate along single-stranded DNA (ssDNA). In contrast, structural data available for SF2 helicases suggest that these enzymes bind nucleic acids rather via contacts with the phosphodiester backbone, which would allow the helicase motor to translocate on both single-stranded DNA (ssDNA) and double-stranded DNA (dsDNA) (4). In agreement with the structural data, ATP hydrolysis by SF1 helicases is stimulated only by ssDNA, whereas the ATPase activity of SF2 helicases is stimulated by both ssDNA and dsDNA (4).

The proposed base-flipping mechanism of ssDNA translocation by PcrA helicase has been examined using DNA substrates containing vinylphosphonate internucleotide linkages, which confer reduced rotational flexibility to the DNA backbone with minimal steric hindrance (17). In agreement with the model derived from structural studies, vinylphosphonate linkages have been found to completely inhibit the helicase activity of PcrA as long as they are situated in the translocating

We present evidence that vinylphosphonate internucleotide linkages inhibit the helicase activity of both BLM and WRN as long as they are placed on the translocating strand. The observed inhibitory effect is not as drastic as in the case of PcrA but nevertheless it is significant. Moreover we show that the human ssDNA-binding factor replication protein A (RPA) alleviates the inhibitory effect of vinylphosphonate modifications on BLM- and WRN-mediated unwinding, whereas it does not affect the PcrA-catalyzed reaction. We conclude that the rotational backbone flexibility of the DNA substrate is important for the action of the BLM and WRN helicases. The mechanism of DNA translocation by these enzymes may involve some base flipping but it is not based entirely on base-flipping as is the case of the SF1 PcrA helicase.

DNA substrates

Unmodified oligonucleotides were purchased from Microsynth (Switzerland) and purified by PAGE. The sequences of the oligonucleotides used were as follows (5' to 3'): VP7 (45mer), TCAAAGTCACGACCTAGACAATCCCCAAAA-AAAAAGCTCGAATTC; VP8 (45mer), TCAAAGTCACGACCTAGACAAGCTCGAATTCGTAATCATGGTCAT; VP9 (59mer), TCAAAGTCACGACCTAGACAATCCCCAAAA-AAAAAGCTCGAATTCGTAATCATGGTCAT; VP10 (38mer), TCTAGAGGATCCCCAAAAAAGACAGCTT-ATGACATTA; VP11 (19mer), TGCATGCCTGCAGGTCGAC; RB15 (66mer), ATGACCATGATTACGAATTCGAGCTTT-TTTTTGGGGATCCTCTAGAGTCGACCTGCAGGCATGCA. A derivative of RB15, named 4mod, containing a tandem of four vinylphosphonate internucleotide linkages ATGACCATGATTACGAATTCGAGCTT*TT*TT*TT*TTGGGGATCCTCTAGAGTCGACCTGCAGGCATGCA; positions of modifications are indicated by asterisks) was synthesized using 5'-DMTO-T*2'-3'CEP phosphoramidite building blocks as described previously (17). It was purified using ABI OPC cartridges according to the manufacturer's

Name	Oligonucleotides	Schematic
A1	VP7 + RB15	
A2	VP7 + 4mod	
B1	VP8 + RB15	
B2	VP8 + 4mod	
C1	VP9 + RB15	
C2	VP9 + 4mod	
D1	VP10 + VP11 + RB15	
D2	VP10 + VP11 + 4mod	

instructions. To prepare the splayed-arm DNA substrates shown in Table 1, the VP7, VP8, VP9 and VP10 oligonucleotides were radioactively labeled at the 5' end using T₄ polynucleotide kinase (New England Biolabs) and [γ -³²P]ATP (Amersham Pharmacia Biotech), and annealed to either RB15 (unmodified substrates) or 4mod (modified substrates) under previously described conditions (23).

BLM⁶⁴²⁻¹²⁹⁰, WRN and PcrA helicases were prepared as previously described (23–26). *Escherichia coli* single-stranded DNA binding (SSB) protein was purchased from Promega. Human RPA was prepared essentially as described in (27). Concentrations of proteins are expressed in moles of monomer except for RPA, which is expressed in moles of heterotrimeric complex.

Reactions were carried out at 37°C in a buffer containing 50 mM Tris-HCl (pH 7.5), 50 mM NaCl, 2 mM MgCl₂, 2 mM ATP, 1 mM DTT and 50 µg/ml BSA. Reaction mixtures contained 1 nM 5' ³²P-labeled DNA substrate and 20 nM BLM⁶⁴²⁻¹²⁹⁰ or 5 nM WRN. Control reactions with 100 nM PcrA and 0.5 nM DNA substrate were carried out in a

buffer containing 20 mM Tris (pH 7.5), 10 mM MgCl₂, 50 mM NaCl, 4 mM DTT, 2.5 mM ATP. Where required, RPA was added to a concentration of 24 nM and SSB to a concentration of 120 nM. Reactions were started with enzyme. Aliquots of 10 μ l were removed at indicated time points and mixed with 5 μ l of stop solution containing 150 mM EDTA, 2% (w/v) SDS, 30% (v/v) glycerol and 0.1% (w/v) bromophenol blue. The reaction mixtures were resolved on 10% (w/v) polyacrylamide gels (acrylamide to bis-acrylamide ratio 19:1) run in TBE buffer (90 mM Tris-borate, pH 8.3, and 2 mM EDTA) at 7 V/cm and room temperature. Radiolabeled DNA species were visualized by autoradiography and quantified using a Molecular Dynamics Typhoon 9400 scanner with associated IMAGEQUANT software. The relative concentration of displaced products was expressed as a percentage of total DNA.

RESULTS

Inhibition of the DNA helicase activity of BLM by vinylphosphonate internucleotide linkages in the translocating strand

To investigate the effect of vinylphosphonate internucleotide linkages on the helicase activity of BLM, we prepared a series of splayed-arm DNA substrates containing four consecutive modifications either in the translocating or displaced strands at varying positions relative to the single-strand/double-strand junction (Table 1). A fragment of BLM comprising the helicase catalytic core (residues 642–1290, BLM^{642–1290}) was used in these experiments. This variant was found to exhibit a similar specific activity as the full-size BLM protein on a number of DNA structures including splayed arm (23). Using a simple gel-based, oligonucleotide displacement assay, we observed that the BLM^{642–1290}-mediated unwinding of a 25 bp duplex was inhibited when the modifications were located inside the duplex region on the translocating strand (Figure 1A and B). Modifications incorporated just prior to the duplex on the translocating strand also reduced the helicase activity of BLM^{642–1290} though to a much lesser extent than the modifications inside the duplex (Figure 1C and D). No inhibitory effect was apparent when the modifications were present on the displaced strand inside the duplex (Figure 1E). Overall, these data indicate that restricting the rotational DNA backbone flexibility in the translocating DNA strand impairs BLM-mediated DNA unwinding.

RPA relieves the inhibitory effect of vinylphosphonate internucleotide linkages on BLM-mediated DNA unwinding

The human RPA has been shown to specifically promote unwinding of long DNA duplexes by BLM and WRN. This stimulatory effect is mediated by physical interaction between RPA and these helicases (28,29). We set up to determine whether RPA can alleviate the inhibitory effect of vinylphosphonate internucleotide linkages on the helicase activity of BLM. In these experiments, we used 39 bp forked duplex substrates with or without four consecutive modifications on the translocating strand located inside the duplex (Table 1; substrates C1 and C2). Under the conditions used,

BLM^{642–1290} alone could only partially unwind the unmodified substrate and showed no detectable helicase activity on the modified substrate (Figure 2A; compare lanes 2 and 9). In contrast, in the presence of RPA, both unmodified and modified substrates were unwound by BLM^{642–1290} efficiently (Figure 2A; lanes 3 and 10). Substitution of RPA with the *E.coli* SSB protein also resulted in a stimulation of BLM-catalyzed unwinding of both modified and unmodified substrates, but to a lesser extent than in the case of the RPA-promoted reactions (Figure 2A; lanes 4 and 11). Time-course experiments revealed that the RPA-promoted unwinding reaction on the modified substrate displayed similar kinetics as that with unmodified substrate (Figure 2B and C). Thus, these data indicate that RPA completely relieves the inhibitory effect of vinylphosphonate internucleotide linkages on BLM-catalyzed DNA unwinding.

Single-stranded DNA binding proteins do not stimulate the helicase activity of PcrA on DNA substrates containing vinylphosphonate linkages

As mentioned above the helicase activity of PcrA has been shown to be inhibited by vinylphosphonate internucleotide linkages located in the translocating DNA strand (18). In agreement with these findings, the 39 bp splayed arm substrate containing modifications inside the duplex region was not unwound by PcrA, although unmodified substrate was unwound efficiently (Figure 3A, B and C). In contrast to BLM, RPA did not alleviate the inhibitory effect of vinylphosphonate modifications on PcrA-mediated DNA unwinding reaction (Figure 3D). In addition, PcrA helicase activity on modified substrate was not stimulated by *E.coli* SSB protein (data not shown). These data provide further evidence that the RPA-promoted bypass of regions containing vinylphosphonate internucleotide linkages by BLM is a specific reaction.

Effect of vinylphosphonate internucleotide linkages on the helicase activity of WRN

Next we sought to examine whether other RecQ DNA helicases display the same characteristics as BLM on DNA substrates containing vinylphosphonate internucleotide linkages. To this end, we tested the WRN helicase for the ability to unwind these substrates in the absence and presence of RPA. Similar to BLM, we found that vinylphosphonate modifications significantly reduced the helicase activity of WRN if located in the translocating strand (Figure 4A and B), but did not produce an inhibitory effect when located on the displaced strand (Figure 4D). In fact, the substrate with modifications in the displaced strand was unwound by WRN more efficiently than the corresponding unmodified substrate. This could be explained partly by an assumption that the vinylphosphonate modifications decrease somewhat the stability of the DNA duplex, since DNA melting studies have revealed that such modifications decrease the melting temperature of DNA duplexes by $\sim 3.5^\circ\text{C}$ per modification (data not shown). In the case of BLM, such striking differences was not apparent as the reactions were nearly completed at the first time point analyzed (Figure 1E). It should also be emphasized that these modifications do not affect the overall structure of normal B-DNA as revealed by NMR studies (18).

Figure 1. Effect of vinylphosphonate internucleotide linkages on helicase activity of BLM⁶⁴²⁻¹²⁹⁰. (A) Kinetics of unwinding of 1 nM A1 (left panel) and 1 nM A2 (right panel) by 20 nM BLM⁶⁴²⁻¹²⁹⁰. (B) Quantification of the reactions shown in (A). Data points represent mean values from three independent experiments. (C) Kinetics of unwinding of 1 nM B1 (left panel) and 1 nM B2 (right panel) by 20 nM BLM⁶⁴²⁻¹²⁹⁰. (D) Quantification of the reactions shown in (C). Data points represent mean values from three independent experiments. (E) Kinetics of unwinding of 1 nM D1 (open circles) and 1 nM D2 (filled circles) by 20 nM BLM⁶⁴²⁻¹²⁹⁰. The graph shows mean values from three independent experiments. All reactions were carried out at 37°C and analyzed as described in Materials and Methods. The relative concentration of the strand-displacement products is expressed as a percentage of total DNA. Lanes labeled with triangles contain heat-denatured substrate. DNA substrates are shown in Table 1.

The inhibitory effect of vinylphosphonate modifications on VRN-catalyzed unwinding was lost upon addition of RPA (Figure 4C), again highlighting differences between RecQ helicases and PcrA in the mode of DNA translocation.

DISCUSSION

Based on amino acid sequence homology, the RecQ proteins belong to the SF2 superfamily of helicases (5). Several crystal structures of SF2 helicases, including *E. coli* RecQ (16), HCV NS3 (15,30), UvrB (31), RecG (13) and eIF4a (32) have been solved and revealed structural similarities, but also intriguing differences from the SF1 helicases PcrA (6,33) and Rep (14). While the SF1 helicases interact with ssDNA using mainly hydrophobic interactions with the DNA bases, the SF2 helicases seem to interact with the DNA via non-specific

electrostatic interactions with the phosphodiester backbone (4,34). These differences may reflect mechanistic differences, with SF1 helicases apparently able to translocate along ssDNA and the SF2 helicases along both ssDNA and dsDNA.

The translocation mechanism of helicases has been a contentious issue (35), but in the case of PcrA a base-flipping unidirectional mode of translocation with one ATP molecule utilized per base translocated has been suggested (6,36). The base-flipping mechanism requires the DNA base to flip in and out of certain pockets on the surface of the protein as it moves along the ssDNA, which is enabled by rotational flexibility of the DNA backbone. Consistent with this model, restricting backbone rotational freedom by introducing vinylphosphonate internucleotide linkages has a detrimental effect on the PcrA helicase activity (18). Vinylphosphonate backbone modifications do not affect regular bending and 'stiffness' of DNA, unless there are sharp kinks induced by the translocating

Figure 2. Single-stranded DNA binding proteins promote unwinding of vinylphosphonate-containing DNA substrates by BLM^{642–1290}. **(A)** Effect of 24 nM human RPA and 120 nM *E. coli* SSB on unwinding of 1 nM C1 and 1 nM C2 by 20 nM BLM^{642–1290}. helicase that also require rotational backbone freedom. There is no structural or functional evidence that such sharp kinks are part of the translocation mechanism of any helicase.

Helicases that interact with DNA mainly via the phosphodiester backbone, such as the SF2 HCV NS3 (Eckhard Jankowsky, personal communication) and RecG (Robert G. Lloyd, personal communication), are able to translocate over vinylphosphonate modifications without apparent problems. In contrast, here we show that two other SF2 helicases, BLM and WRN, are inhibited by vinylphosphonate modifications. As these modifications in the A2 and C2 substrates reside inside the duplex region, it is unlikely that they will inhibit the initial binding of BLM and WRN proteins to the ssDNA/dsDNA junction. Instead, the inhibition must be related to the actual translocation process. Although the inhibitory effect of vinylphosphonate internucleotide linkages on BLM- and WRN-mediated DNA unwinding is not as drastic as that observed for PcrA, it is significant, suggesting that rotational DNA backbone freedom is an essential requirement for efficient helicase activity in these helicases. Therefore, the translocation mechanism of BLM and WRN seems to involve

some base-flipping aspect, as in PcrA, but it is not entirely dependent on base-flipping, unlike PcrA (partial inhibition versus complete inhibition). As mentioned above, other SF2 helicases such as HCV NS3 and RecG are unaffected by vinylphosphonate modifications, suggesting that their mechanism of translocation does not involve base-flipping and is instead based upon interaction with the phosphodiester backbone in agreement with structural studies. Moreover, the SF2 helicase NPH-II has been recently shown to tolerate abasic sites in the translocating strand, while it essentially requires physical continuity of the phosphodiester linkage, again suggesting a mechanism in which the protein makes contact with the sugar-phosphate backbone during translocation (37). The recent crystal structure of the *E. coli* RecQ revealed a patch of conserved aromatic and charged residues (residues 156–159, C-terminal to motif II) mapping to the same relative surface location as similar residues in PcrA that are used in DNA binding (residues 257–260, C-terminal to motif III) (16). This structural feature suggests that *E. coli* RecQ may utilize a combination of base-flipping and phosphodiester backbone interactions to translocate along ssDNA, although the structure

(D) Kinetics of unwinding of 1 nM D1 (open circles) and 1 nM D2 (filled circles) by 5 nM WRN. Reactions were carried out at 37°C and analyzed as described in Materials and Methods. The relative concentration of the strand-displacement products is expressed as a percentage of total DNA. Data points represent mean values from three independent experiments. DNA substrates are shown in Table 1.

of RecQ complexed with DNA is required to confirm these observations.

The stimulatory effect of RPA on BLM- and WRN-mediated unwinding of vinylphosphonate-containing DNA substrates and the failure of RPA to stimulate PcrA imply a specific interaction between RPA and both BLM and WRN helicases. This is further supported by the fact that heterologous SSB from *E. coli* stimulated BLM and WRN helicases on modified substrates only marginally. This effect is likely to reflect a simple non-specific trapping of displaced strands by SSB. BLM and WRN helicases exhibit a very low processivity (28,29). RPA has been shown to specifically stimulate BLM- and WRN-mediated unwinding through direct protein-protein interactions (28,29). It has been postulated that in addition to trapping displaced single-strands, RPA may tether the helicase to the DNA substrate at the single-strand/double-strand junction to facilitate the progression of the enzyme through relatively long DNA duplex tracts (28,29). Such a mechanism would explain the observed stimulatory effect of RPA on BLM- and WRN-mediated unwinding of vinylphosphonate-linked substrates. Providing that the modifications cause a pause in enzyme translocation followed by its dissociation from the DNA substrate, one can assume that tethering the enzyme to the translocating strand via interaction with ssDNA-bound RPA would allow it to cope with a more rotationally rigid region in the DNA template during the unwinding reaction.

Our study provides evidence of subtle differences and similarities between SF1 and SF2 helicases. Although RecQ helicases belong to SF2, they appear to be different from other SF2 helicases such as HCV NS3, RecG and NPH-II. They may translocate along ssDNA by using a combination of base-flipping (characteristic of the SF1 PcrA helicase) and non-specific phosphodiester-backbone interactions (characteristic of SF2 HCV NS3, RecG and NPH-II helicases). In that sense RecQ helicases may mechanistically belong to a sub-family of SF2 helicases.

ACKNOWLEDGEMENTS

We thank Richard Bertram and John Keyte for help with the preparation of vinylphosphonate DNA substrates. This work was supported by a Swiss National Science Foundation grant to P.J. and a Wellcome Trust grant (064751/Z/01/Z) to P.S.

Bloom's syndrome is a hereditary cancer-predisposition disorder resulting from mutations in the *BLM* gene. In humans, *BLM* encodes one of five members of the RecQ helicase family. One function of BLM is to act in concert with topoisomerase III α (TOPO III α) to resolve recombination intermediates containing double Holliday junctions by a process called double Holliday junction dissolution, herein termed dissolution. Here, we show that dissolution is highly specific for BLM among human RecQ helicases and critically depends upon a functional HRDC domain in BLM. We show that the HRDC domain confers DNA structure specificity, and is required for the efficient binding to and unwinding of double Holliday junctions, but not for the unwinding of a simple partial duplex substrate. Furthermore, we show that lysine-1270 of BLM, which resides in the HRDC domain and is predicted to play a role in mediating interactions with DNA, is required for efficient dissolution.

Introduction

Mutations in the *BLM* gene give rise to Bloom's syndrome (BS) in humans (Ellis *et al*, 1995). This rare genetic disorder is characterized by short stature, sunlight sensitivity, immunodeficiency and a predisposition to the development of many different types of malignancies (Bachrati and Hickson, 2003; Hickson, 2003). *BLM* encodes a DNA helicase that belongs to

a highly conserved family, the prototypical member of which is encoded by the *recQ* gene of *Escherichia coli* (Figure 1A) (Bachrati and Hickson, 2003). Germline mutations in two other human RecQ family helicase genes also give rise to cancer-predisposition disorders: *WRN* mutations give rise to Werner's syndrome and *RECQ4* mutations are associated with some cases of Rothmund–Thomson syndrome (Yu *et al*, 1996; Kitao *et al*, 1999).

The existence of clinically distinct disorders associated with inactivation of any of three different RecQ family helicases indicates that the human RecQ family helicases have specialized functions in the cell (Oakley and Hickson, 2002; Bachrati and Hickson, 2003; Wang *et al*, 2003). In the budding yeast, *Saccharomyces cerevisiae*, mutation of the sole RecQ helicase gene, *SGS1*, results in elevated levels of genome-wide genetic recombination (Gangloff *et al*, 1994; Watt *et al*, 1996). This role in regulating homologous recombination levels appears to have been conserved in humans, at least in the case of BLM, since BS cells also show excessive levels of genome-wide homologous recombination. This is particularly apparent for recombination events between sister chromatids, giving rise to a characteristically elevated level of sister chromatid exchanges (SCEs) that is sufficiently specific for BS to be used in the diagnosis of the disorder (Chaganti *et al*, 1974). The hyper-recombination phenotype of certain RecQ helicase mutants is likely due to aberrant processing of recombination intermediates (Wu and Hickson, 2002b) since RecQ helicases from several organisms have been purified, and have been shown to act upon DNA intermediates that arise during the process of homologous recombination (Bachrati and Hickson, 2003).

RecQ helicases all contain a conserved helicase domain that defines the family (Bachrati and Hickson, 2003). There are, however, additional sequence motifs that flank the signature helicase domain (Figure 1A). In certain cases, additional enzymatic activities reside in these flanking domains. In the case of *WRN*, a 3'–5' exonuclease domain is located in the N-terminal region, whereas the C-terminal domain of *RECQ5 β* directs a DNA strand annealing function (Huang *et al*, 1998; Kamath-Loeb *et al*, 1998; Garcia *et al*, 2004) (Figure 1A). Other sequence motifs identified in RecQ helicases include the RQC domain, which is situated C-terminal to the helicase domain and appears to be found exclusively in some RecQ helicases, and the HRDC domain, which is found C-terminal to the RQC domain of some RecQ helicases and in RNaseD homologs (Figure 1A and B) (Bachrati and Hickson, 2003). The structures of the RQC and HRDC domains have been determined for RecQ and Sgs1, respectively (Liu *et al*, 1999; Bernstein *et al*, 2003). The RQC domain resembles a so-called winged-helix domain, which is a member of the helix–turn–helix superfamily, and plays a role in binding duplex DNA (Bernstein *et al*, 2003). Interestingly, in BLM and WRN, the RQC domain has been implicated also in the orchestration of protein–protein interactions (Brosh *et al*, 2001; von Kobbe *et al*, 2002; Bachrati and

Role of the BLM HRDC domain in double Holliday junction dissolution L Wu *et al*

Figure 1 (A) Schematic representation of selected members of the RecQ helicase family. All proteins are from humans, except *E. coli* RecQ and *S. cerevisiae* Sgs1, and are aligned about the conserved helicase domain. Also shown are the relative positions of the exonuclease (Exo) and ssDNA annealing domains of WRN and RECQ5β, respectively, and the RQC (R) and HRDC domains. Nonconserved regions are shaded in gray. Relevant amino-acid residue positions of truncation mutants used in this study are indicated above BLM and RecQ. See text for details. (B) Alignment of the HRDC domain of BLM, WRN, Sgs1 and *E. coli* RecQ. Residues comprising α-helices in the three-dimensional structure of Sgs1 are indicated by boxes above. Identical or similar residues are shaded in gray. Shown below is the amino-acid substitution K1270V used in the generation of BLM(K1270V). See text for details. The figure was adapted from Liu *et al* (1999).

Hickson, 2003). The HRDC domain is thought to function as an auxiliary DNA-binding domain and, structurally, it resembles domains found in many DNA-metabolizing enzymes such as helicases, polymerases and recombinases (Morozov *et al*, 1997; Liu *et al*, 1999). How these conserved motifs impact on the biochemical properties of RecQ helicases and affect the *in vivo* function of these enzymes has not been determined.

In addition to the presence or absence of the aforementioned functional domains, the different cellular functions of the various vertebrate RecQ helicases likely depend on their ability to form specific interactions with different protein partners. BLM is proposed to act in a complex with replication protein A and the type IA topoisomerase, topoisomerase IIIα (hTOPO IIIα) (Brosh *et al*, 2000; Johnson *et al*, 2000; Wu *et al*, 2000; Meetei *et al*, 2003). This association with a type IA topoisomerase is evolutionarily conserved, since Sgs1p also acts together with Top3p, the only type IA topoisomerase expressed in budding yeast (Gangloff *et al*, 1994; Bennett and Wang, 2001; Fricke *et al*, 2001). *top3* mutant cells have elevated levels of recombination (Wallis *et al*, 1989), which can be suppressed, at least partially, by inactivation of either Sgs1p or Rad52p, the latter of which is required for all forms of homologous recombination (Gangloff *et al*, 1994; Oakley *et al*, 2002; Shor *et al*, 2002). The conserved coupling of a RecQ helicase and a type IA topoisomerase, therefore, appears to have a central role in regulating recombination levels

in the cell (Wu and Hickson, 2001). In particular, Sgs1p and BLM appear to suppress the formation of crossover products that arise from the resolution of homologous recombination intermediates containing Holliday junctions (Ira *et al*, 2003; Wu and Hickson, 2003). We have recently proposed a mechanism by which this is achieved by BLM. Together with hTOPO IIIα, BLM can catalyze double Holliday junction dissolution (DHJ), a reaction mechanism in which DHJs are resolved exclusively into non-crossover recombinant products (Wu and Hickson, 2003). Here, we have demonstrated that BLM cannot be substituted by other RecQ helicases in dissolution reactions containing hTOPO IIIα. Furthermore, we reveal the first biochemical function for the HRDC domain of a RecQ helicase through the demonstration of a requirement for this domain in the specific recognition, processing and dissolution of DHJs.

Results

Double Holliday junction dissolution is specific for BLM

Despite the similar biochemical properties of many RecQ helicases *in vitro*, and their ability to act upon a wide variety of DNA structures, an elevated frequency of SCEs is thought to be a feature unique to BLM-deficient cells among human RecQ helicase mutants. We set out, therefore, to examine the apparent contradiction between, on the one hand, the promiscuous and redundant biochemical activities of RecQ

helicases *in vitro* and, on the other, the distinct cellular phenotypes of RecQ helicase mutants. To do this, we analyzed the ability of three other human RecQ helicases to catalyze dissolution in conjunction with hTOPO III α . Dissolution was assessed using an oligonucleotide-based molecule (DHJ) that we had used previously to assay for dissolution activity (Figure 2) (Fu *et al*, 1994; Wu and Hickson, 2003). Using this substrate, we found that WRN, RECQ1 and RECQ5 β could not substitute for BLM in dissolution reactions with hTOPO III α , indicating that the reaction mechanism of dissolution displays a high degree of specificity for BLM (Figure 3).

The N-terminal domain of BLM is not required to catalyze dissolution

The apparently specific ability of BLM to catalyze dissolution indicated that the BLM protein itself must possess biochemical functions that are not present in the other human RecQ helicases. To identify structural features of BLM that are required for catalysis of dissolution, we generated a series

Figure 2 Outline of the strategy used in the generation of the DHJ-containing substrates analyzed in this study, DHJ and DHJ/Rsa1. DHJ comprises two oligonucleotides (B1 and R1), each of which contains two regions of complementary sequences giving rise to two 11 bp internal duplex arms. When incubated together, B1 and R1 anneal to form a molecule that contains two juxtaposed HJs separated by two 14 bp heteroduplex regions (Fu *et al*, 1994; Wu and Hickson, 2003). These heteroduplexes contain approximately 1.5 helical turns, which results in the catenation of B1 and R1 when both oligonucleotides are circularized by ligation. Topologically relevant helical turns are shown. Each oligonucleotide can be detected individually by the 5' end-labeling of one of the oligonucleotides prior to annealing. In this scheme, oligonucleotide R1 has been labeled, as indicated by the asterisk. Blue arrows indicate the enzymatic activity each substrate was used to assess and the detectable product generated from each substrate. Dissolution of DHJ results in the decatenation of B1 and R1 releasing the two oligonucleotides as circular DNA species, each of which has a faster mobility on denaturing PAGE than the DHJ substrate (Wu and Hickson, 2003). Unwinding of DHJ/Rsa1 by BLM releases linear R1 and circular B1.

of truncated versions of BLM that all retained the catalytic core of BLM (Figure 1) and assessed the ability of these BLM variants to catalyze dissolution. Residues 1–133 of BLM contain an hTOPO III α -interaction domain (Hu *et al*, 2001). We therefore wanted to determine if this interaction domain was required for dissolution. Deletion of residues 1–212 of BLM, and thus removal of this hTOPO III α -interaction domain, did not affect the ability of BLM to catalyze dissolution (Figure 4A). Moreover, a truncated BLM protein generated by removal of the entire nonconserved N-terminal domain of BLM (residues 1–641) was still able to catalyze dissolution (data not shown). Dissolution of DHJ is a symmetrical reaction and generates two circular products in an ATP-dependent manner. To eliminate the possibility that both of the N-terminally truncated proteins catalyze a pseudodissolution reaction by, for instance, asymmetric nicking of the substrate in the unlabeled oligonucleotide, we monitored the

Figure 3 Dissolution is specifically catalyzed by BLM. Dissolution reactions containing a series of two-fold dilutions of BLM (upper panel, 5, 2.5, 1.25, 0.625, 0.3125, 0.15 and 0.075 nM; the middle and lower panels did not contain the three and two lowest concentrations, respectively), WRN (15, 7.5, 3.75, 1.87, 0.94, 0.47 and 0.24 nM), RECQ1 (100, 50, 25 and 12.5 nM) or RECQ5 β (80, 40, 20, 10 and 5 nM), as indicated above the panels. Lanes containing hTOPO III α (250 nM) are indicated above by black bars. Positions of the DHJ substrate and the dissolution product are shown on the left. For simplicity, the intertwining of the strands of DHJ is omitted.

Role of the BLM HRDC domain in double Holliday junction dissolution L Wu *et al*

Figure 4 The C- but not the N-terminal domain of BLM is required for dissolution. (A) Dissolution reactions in the presence or absence of 5 mM ATP and containing hTOPO III α and full-length BLM(1–1417) or BLM(213–1417), as indicated. In the DHJ substrate, oligonucleotide R1 is labeled. Positions of the DHJ substrate, dissolution product and products of the indicated restriction digests, confirming the identity of the labeled oligonucleotide, are shown on the left. (B) Identical reactions to those shown in (A) were carried out except that a DHJ molecule was used in which oligonucleotide B1 was labeled. (C) Dissolution reactions containing a series of two-fold dilutions of BLM (highest concentration, 5 nM) or BLM(213–1267) (highest concentration, 7 nM). Lanes containing hTOPO III α (250 nM) are indicated by black bars. Positions of the DHJ substrate and dissolution product are shown on the left.

fate of both oligonucleotides by performing dissolution reactions on the two forms of DHJ in which either oligonucleotide R1 or B1 was labeled. The reaction catalyzed by both of the N-terminal BLM truncation mutants on each DHJ substrate was indistinguishable from that carried out by full-length BLM with regard to ATP dependency and the structure of the reaction products, that is, two intact circular species (Figure 4A and B and data not shown). Together, these data indicate that the N-terminal domain of BLM, and thus a physical

Figure 5 The C-terminal domain of BLM is required for efficient unwinding of DHJs. Helicase assays using DHJ/Rsa1 and a series of two-fold dilutions of BLM, BLM(213–1417) or BLM(213–1267) on DHJ/Rsa1, as indicated. The positions of DHJ/Rsa1 and the unwound product are shown on the right. The graph shows quantification of the level of unwound product generated by BLM (circles), BLM(213–1417) (squares) and BLM(213–1267) (triangles) on DHJ/Rsa1. Note that the scale on the horizontal axis is logarithmic.

association of hTOPO III α with this portion of BLM, is not required for the catalysis of dissolution.

The C-terminal domain of BLM is essential for dissolution

The dispensable nature of the N-terminal domain of BLM for dissolution led us to examine the role of the C-terminal domain of BLM using a previously described, truncated version of BLM that consists of residues 213–1267, herein designated BLM(213–1267) (Wu and Hickson, 2002a). Despite being an active helicase, we found that BLM(213–1267), in contrast to BLM(213–1417), which contains the natural C-terminus of BLM, was defective in catalyzing dissolution (Figure 4C). This indicates that in addition to the helicase domain, residues 1268–1417 of BLM are required for dissolution (Figure 4).

The RecQ family HRDC domain is required for the binding to and unwinding of double Holliday junctions

The deletion of residues 1268–1417 to generate BLM(213–1267) resulted in truncation of the HRDC domain, which consists of residues 1210–1290 in BLM (Figure 1A and B). We reasoned, therefore, that the failure of BLM(213–1267) to catalyze dissolution might be reflected in a diminished ability to interact with and/or process DHJs as a result of the inactivation of the DNA-binding function of the BLM HRDC domain. To address this, we compared the ability of BLM and BLM(213–1267) to unwind, in the absence of hTOPO III α , a modified DHJ molecule (DHJ/Rsa1) in which DHJ had been digested with Rsa1 (Wu and Hickson, 2003). The linearization of oligonucleotide R1 by Rsa1 results in the topological unlinking of the two constituent oligonucleotides of DHJ and thus creates a substrate that can be disrupted by thermal denaturation or by a helicase activity (Figure 2) (Wu and Hickson, 2003). The intact DHJ substrate is resistant to conventional unwinding due to its covalently closed nature. While we found that both BLM and BLM(213–1267) were able to unwind DHJ/Rsa1, BLM(213–1267) displayed an approximately 10-fold reduction in helicase activity toward this substrate compared to that of full-length BLM (Figure 5).

This impaired helicase activity was solely due to the loss of residues 1268–1417 of BLM, since BLM(213–1417), which lacks only the N-terminal 1–212 residues, displayed helicase activity on this substrate that was equivalent to that displayed by full-length BLM (Figure 5).

One possible explanation for the reduced helicase activity displayed by BLM(213–1267) was that the truncated protein has a reduced affinity for DHJs. To analyze this, we employed two independent means to compare the binding affinities of BLM(213–1417) and BLM(213–1267) for the DHJ substrate: a filter-binding assay, in which we measured protein-dependent retention of DHJ on a nitrocellulose membrane, and an electrophoretic mobility shift assay (EMSA), in which potentially different protein/DHJ complexes were visualized as a result of their reduced electrophoretic mobility compared to protein-free DHJ. Using the filter-binding assay, we found that BLM(213–1267) had a significantly reduced ability to bind DHJ as compared to BLM(213–1417) (Figure 6A). Using EMSAs, BLM(213–1417) was found to generate two differentially retarded species and a small amount of material that could not be resolved and was retained in the gel wells (Figure 6B). The level of all retarded species was dramatically reduced when BLM(213–1267) replaced BLM(213–1417) in the EMSA analyses (Figure 6B), thus confirming the conclusion of the filter-binding assay.

Figure 6 The C-terminal domain of BLM is required for efficient binding to DHJs. (A) DNA filter-binding assay using a series of two-fold dilutions of BLM(213–1417) or BLM(213–1267) on DHJ. The graph shows the quantification of the relative level of DNA bound to the filter in reactions containing either BLM(213–1417) (squares) or BLM(213–1267) (triangles). (B) DNA EMSA using a series of two-fold dilutions of BLM(213–1417) or BLM(213–1267) on DHJ, as indicated above the lanes. The positions of the unbound substrate and protein-DNA complexes (black arrowheads) are indicated on the right. The graph shows the quantification of the total amount of DNA bound by BLM(213–1417) (squares) or BLM(213–1267) (triangles).

Next, we addressed the question of whether the observed reduction in DNA-binding affinity and helicase activity of BLM(213–1267) was specific for DHJ structures. To do this, we compared the helicase activities of BLM, BLM(213–1417) and BLM(213–1267) on a conventional helicase substrate, a forked partial duplex. Interestingly, all three proteins displayed very similar levels of helicase activity on this substrate and, in contrast to the results with the DHJ substrate, BLM and BLM(213–1267) displayed similar binding affinities for the forked duplex substrate (Figure 7). Together, these data strongly suggest that the C-terminal domain of BLM contains a DNA structure-specific binding motif, and implicate residues 1268–1417 of BLM in the processing of DHJ structures.

To provide further support for the proposal that it is loss of the HRDC domain that is responsible for the reduced ability of BLM(213–1267) to unwind DHJ/*Rsa1*, a comparison was made between the activities of *E. coli* RecQ and a truncated version of this protein (residues 1–523) that lacks the entire HRDC domain, RecQ(1–523) (Figure 1A and B) (Bernstein and Keck, 2003). Both proteins were able to unwind DHJ/*Rsa1* to some extent, but RecQ(1–523) had a much reduced ability to unwind this molecule compared to full-length RecQ (> 10-fold reduction; Figure 8). As was the case with BLM, loss of the RecQ HRDC domain appeared to specifically affect the helicase activity of RecQ on the DHJ/*Rsa1* substrate since

Figure 7 The C-terminal domain of BLM is not required for the unwinding or binding of forked duplexes. (A) Helicase assays using a series of two-fold dilutions of BLM, BLM(213–1417) and BLM(213–1267) on a forked partial duplex substrate. The positions of the forked duplex and the unwound product are shown on the right. The graph shows quantification of the amount of unwound product generated by BLM (circles), BLM(213–1417) (squares) or BLM(213–1267) (triangles). (B) DNA filter-binding assay using a series of two-fold dilutions of BLM or BLM(213–1267) on a forked partial duplex substrate. The graph shows quantification of the relative amount of DNA bound to the filter in reactions containing BLM(213–1417) (squares) or BLM(213–1267) (triangles).

Role of the BLM HRDC domain in double Holliday junction dissolution

L Wu *et al*

Figure 8 The *E. coli* RecQ HRDC domain is required for the unwinding of DHJ/Rsa1 but not of a forked duplex. Helicase assays using RecQ and RecQ(1–523) on either DHJ/Rsa1 (left) or a forked partial duplex (right) substrate. The graphs show the quantification of unwound product for each substrate for RecQ (circles) and RecQ(1–523) (squares). Note that the scale on the horizontal axis is logarithmic.

it had no significant effect on its helicase activity on a forked DNA substrate (Figure 8). These data suggest a conserved function for the HRDC domain of RecQ family helicases in the specific processing of DHJs. The fact that the RecQ and BLM HRDC domains apparently have similar functions in facilitating the efficient unwinding of DHJ/Rsa1 raised the possibility that RecQ might also catalyze dissolution together with bacterial Top3. RecQ and Top3 have been shown to cooperate in the mediation of a strand passage activity that facilitates the catenation and decatenation of covalently closed plasmid DNAs (Harmon *et al*, 1999). However, we found that RecQ and Top3 could not catalyze dissolution under conditions that supported dissolution by BLM and hTOPO III α (data not shown).

Lysine-1270 of BLM is required for efficient dissolution activity

Thus far, we conclude that the inability of BLM(213–1267) to catalyze dissolution is likely due to the absence of a functional HRDC domain, which had been inactivated by truncation. However, to demonstrate this directly and to eliminate the possibility that the truncation of the C-terminal 150 residues to generate BLM(213–1267) might have had long-range effects on other portions of the BLM protein and thereby led to inactivation of non-HRDC-mediated functions, we sought to abrogate the HRDC domain function in the context of the full-length protein. The similarity of the predicted secondary structure of the HRDC domain in RecQ helicases to motifs in unrelated DNA-metabolizing enzymes suggests that it is the conserved protein fold of the HRDC domain that is important for function. We set out, therefore, specifically to disrupt the conformation of the HRDC domain in BLM by site-directed mutagenesis. Initial attempts involved either the substitution of proline for the highly conserved alanine-1250 residue in order to destabilize α -helix 2 of the HRDC domain, or the creation of an internal deletion removing residues 1251–1262 to truncate α -helix 2 and remove α -helix 3 (Figure 1B). However, neither of these proteins could be expressed successfully, indicating that disruption of the fold of the HRDC domain likely reduces the solubility and/or stability of BLM. As an alternative, we chose to mutate highly conserved residues that, in the predicted three-dimensional structure of the BLM HRDC domain, reside on the protein surface. We reasoned that such residues

Figure 9 Lysine-1270 is required for efficient catalysis of dissolution. (A) Graph of relative helicase activity for BLM (circles) and BLM(K1270V) (triangles) on a forked partial duplex substrate. (B) Graph of relative dissolution activity catalyzed by BLM (circles) and BLM(K1270V) (triangles) as a function of either protein concentration (left) with a logarithmic scale on the horizontal axis or time in the presence of a fixed protein concentration of 0.8 nM (right).

were less likely to be essential for the overall structural integrity of the HRDC domain, but may be important for function through the mediation of intermolecular interactions. Lysine-1329 of Sgs1 has been shown to contact ssDNA, consistent with the role of the HRDC domain as an auxiliary DNA-binding domain (Liu *et al*, 1999). This residue is conserved among RecQ helicases and corresponds to residue 1270 in BLM (Figure 1B). We therefore mutated the BLM cDNA to convert lysine-1270 to valine in the full-length BLM protein to generate BLM(K1270V). BLM(K1270V) could be expressed and purified to give protein yields that were comparable to those seen with wild-type BLM (data not shown). Purified BLM(K1270V) was active as a helicase, and had a level of activity on a forked partial duplex substrate that was indistinguishable from that of wild-type BLM (Figure 9A). The substitution of lysine-1270 to valine, therefore, did not appear to have any gross effect on the overall stability or the helicase activity of BLM. However, BLM(K1270V) had a substantially reduced ability in comparison with wild-type BLM to support dissolution together with hTOPO III α (Figure 9B). Time-course experiments performed with a fixed concentration of protein indicated an approximately eight-fold reduction in the rate of dissolution for BLM(K1270V) (Figure 9B). Taken together, these data reveal that lysine-1270 of the HRDC domain in BLM is essential for the efficient dissolution of DHJ.

Discussion

A cellular marker of BLM deficiency used in the diagnosis of BS is an abnormally high frequency of spontaneous SCEs. In normal cells, it has been proposed that SCEs are suppressed by the ability of BLM, together with hTOPO III α , to catalyze dissolution. This is an alternative mechanism to that of

endonuclease-mediated resolution of HJs, such as that catalyzed by RuvC, Mus81 or the XRCC3/RAD51C complex (Chen *et al*, 2001; Osman *et al*, 2003; West, 2003; Liu *et al*, 2004). Here, we have shown that despite being one of five highly related human RecQ helicases, BLM could not be substituted by WRN, RECQ1 or RECQ5 β in dissolution reactions containing hTOPO III α . Structurally, proteins of the RecQ helicase family are modular in nature. Several members, including BLM, contain, in addition to the signature helicase domain, a number of identifiable sequence motifs. Previously (and in this study), we have shown that BLM-mediated dissolution requires ATP hydrolysis, indicating a requirement for the helicase domain of BLM in this reaction (Wu and Hickson, 2003). In this study, we have identified the HRDC domain of BLM as also being required for dissolution. The structural similarity of the HRDC domain found in RecQ helicases to domains found in other DNA-metabolizing enzymes strongly indicates a role in mediating contacts with DNA. However, the RecQ helicase HRDC domain is clearly not required for intrinsic helicase activity since we demonstrated that variants of both BLM and RecQ that lack HRDC domains have a helicase activity on forked duplexes that is similar to that of their respective full-length proteins. Rather, we propose that the HRDC domain found in RecQ helicases performs a more specialized role in the recognition of alternate DNA structures, and, more specifically, that it is required for the efficient unwinding of DHJ structures. In particular, we have shown that the amino-acid substitution K1270V in BLM, which is predicted to alter the charge of the DNA-binding face of the HRDC domain, resulted in a diminished ability to mediate dissolution. This is the first specific biochemical function to have been ascribed to the HRDC domain. We did not attempt to complement the hyper-SCE phenotype of BS cells by expression of the *BLM*(K1270V) cDNA since we and others (Ellis *et al*, 1999; Hu *et al*, 2001; Davies *et al*, 2004) have made the observation that complementation with the wild-type *BLM* cDNA is often only partial and results in a broad range of SCE frequencies. Therefore, given that the *BLM*(K1270V) mutant is only partially defective for HRDC function and can still catalyze dissolution, to some extent, we think it is unlikely that any statistically significant difference between *BLM*(K1270V) and BLM to correct the elevated SCEs seen in BS cells will be demonstrable. However, Yankiwski *et al* (2001) have shown that expression of a mutant *BLM* cDNA, which contains an internal deletion that removes the whole of the HRDC domain and thus will be completely defective for HRDC function, is unable to complement the hyper-SCE phenotype of BS cells. This observation is consistent with the proposal that there is a direct link between the dissolution of DHJs and the suppression of SCEs *in vivo*.

While the HRDC domain is necessary for BLM to catalyze dissolution, its presence in other RecQ helicases is not sufficient to facilitate dissolution. One question that arises from this study, therefore, is does the HRDC domain function in a similar manner in those RecQ helicases where it is present or has it evolved different but related auxiliary functions that contribute to the functional diversification of RecQ helicases? Superficially, the BLM and RecQ HRDC domains appear to have a similar role, *in vitro*, in the specific recognition of DHJs. An HRDC domain is also present in WRN. However, unlike BS cells, Werner syndrome cells do

not show obvious alterations in the levels of genome-wide recombination, but do have telomere maintenance defects (Wyllie *et al*, 2000; Crabbe *et al*, 2004). Indeed, in murine models of WS, many of the phenotypes of WS are only manifested in the presence of a second mutation that inactivates telomerase (Chang *et al*, 2004; Du *et al*, 2004). Therefore, one role for WRN may be in a recombination-dependent pathway that acts to maintain telomeres in the absence of telomerase. The HRDC domain of WRN may therefore have evolved a role in the specific recognition of recombination structures that arise at telomeres (Opresko *et al*, 2004). Structural comparisons of the RecQ and Sgs1 HRDC domains indicate that the domain is a highly versatile DNA-binding module that can support several different DNA-binding modes (Liu *et al*, 1999; DA Bernstein and JL Keck, unpublished data). Indeed, the distribution of surface charge of the HRDC domain, to which lysine-1270 of BLM contributes, is quite distinct between Sgs1, BLM and WRN, which is consistent with the notion that the HRDC domain may have evolved different roles in different RecQ helicases (Liu *et al*, 1999, DA Bernstein and JL Keck, unpublished data).

We have demonstrated that the entire N-terminal domain of BLM is dispensable for dissolution. This result was somewhat surprising since this portion of BLM contains an hTOPO III α -interaction domain that is essential *in vivo* for the interaction with hTOPO III α and for the suppression of SCEs (Hu *et al*, 2001). Moreover, a similar functional domain organization exists in Sgs1, where the N-terminal domain of Sgs1p is required for the interaction with Top3p (Gangloff *et al*, 1994; Bennett *et al*, 2000; Fricke *et al*, 2001). One possible explanation for these apparently contradictory *in vitro* and *in vivo* requirements for a physical association of BLM and hTOPO III α is that, *in vivo*, the physical association between hTOPO III α and the N-terminal domain of BLM may facilitate, not a biochemical activity, but rather the recruitment of hTOPO III α to its correct subcellular localization. This proposal is consistent with the mislocalization of hTOPO III α observed in BS cells (Wu *et al*, 2000).

RecQ and Top3, respectively, constitute the sole RecQ helicase family member and topoisomerase III enzyme in *E. coli*. The fact that these two enzymes were unable to catalyze DHJ dissolution suggests that the ancestral function of coupling the activities of a RecQ helicase and topoisomerase III may not be to catalyze dissolution. Indeed, in contrast to BS cells, RecQ mutants have decreased, not increased, levels of crossovers (Kusano *et al*, 1994). Dissolution results exclusively in non-crossover products and therefore suppresses the exchange of genetic material between molecules engaged in the process of homologous recombination. We propose that this mechanism to resolve recombination intermediates evolved with the advent of diploid organisms with large genomes containing repetitive sequences. In such organisms, the suppression of crossover events during recombinational repair is paramount for the prevention of mutagenic genomic rearrangements that can arise when the DNA molecules participating in recombinational repair are nonsisters. In particular, crossing-over in mammalian cells between sequences lying on homologous chromosomes can lead to loss of heterozygosity, a known driver of the tumorigenesis process. Notably, BLM-deficient mice show excessive loss of heterozygosity and accelerated tumor development (Luo *et al*, 2000).

Role of the BLM HRDC domain in double Holliday junction dissolution

L Wu *et al*

In summary, we have shown that the RecQ helicase family HRDC domain confers DNA structure specificity and, in BLM, is required for the dissolution of DHJs. Further analyses to elucidate how the HRDC domain confers structural specificity and how it may function differentially in the various RecQ helicase family members will be crucial in our understanding of the role played by these enzymes in the maintenance of genome integrity and the suppression of tumorigenesis in man.

Materials and methods

Proteins

BLM, BLM (K1270V), BLM(213–1267) and BLM(213–1417) proteins were expressed in yeast and purified by nickel-chelate affinity chromatography using methods described previously (Karow *et al*, 1997). WRN, RECQ1, RECQ5 β , RecQ and RecQ(1–523) were expressed and purified as described previously (Brosh *et al*, 1999; Bernstein and Keck, 2003; Bernstein *et al*, 2003; Cui *et al*, 2004; Garcia *et al*, 2004). The expression construct for BLM(K1270V) was generated by replacing in the yeast expression vector, pJK1, the *HindIII/BamHI* fragment, internal to the BLM cDNA, with a PCR-generated mutant fragment containing the desired single codon substitution. hTOPO III α was a kind gift from Drs Hélène Goulaouic and Jean-François Riou (Goulaouic *et al*, 1999).

DNA substrates

DHJ, DHJ/*RsaI* and partial duplex fork substrates were prepared and purified as described previously (Mohaghegh *et al*, 2001; Wu and Hickson, 2003).

Dissolution and unwinding assays

Reactions were carried out in a buffer containing 50 mM Hepes-KOH, pH 7.2, 50 mM NaCl, 4 mM MgCl₂, 5 mM ATP, 1 mM DTT and various combinations of proteins and DNA substrates, as indicated

in the figure legends. Reactions were incubated at 37°C for 60 min, unless otherwise stated, and stopped by the addition of 1% SDS and 50 mM EDTA. Samples were deproteinized by the addition of proteinase K and a further incubation at 37°C for 15 min. Dissolution and unwinding reactions were subjected, respectively, to 8% denaturing and 10% native PAGE. Gels were dried and subjected to PhosphorImage analysis using a STORM 840 scanner and ImageQuant software.

DNA-binding filter assays

DHJ was incubated with varying concentrations of protein, as indicated in the figure legends, in reaction buffer containing 20 mM triethanolamine-HCl, pH 7.5, 4 mM MgCl₂, 10 μ g/ml BSA, 2 mM ATP γ S and 1 mM DTT at 37°C for 20 min. Reactions containing the forked duplex were performed as described above for the DHJ, with the exception that the reaction buffer contained 2 mM MgCl₂. Reactions were then adsorbed under vacuum onto a nitrocellulose membrane using a dot-blot manifold apparatus. Each reaction spot was then washed with 500 μ l reaction buffer under vacuum before the membrane was air-dried and subjected to PhosphorImage analysis using a STORM 840 scanner and ImageQuant software.

DNA-binding EMSA

DHJ was incubated with varying concentrations of protein, as indicated in the figure legends, in reaction buffer containing 20 mM triethanolamine-HCl, pH 7.5, 4 mM MgCl₂, 10 μ g/ml BSA, 2 mM ATP γ S and 1 mM DTT at 37°C for 20 min. Samples were then fixed by the addition of 0.25% glutaraldehyde before being subjected to 5% PAGE. Gels were dried and subjected to PhosphorImage analysis using a STORM 840 scanner and ImageQuant software.

ABSTRACT

The product of the gene mutated in Bloom's syndrome, BLM, is a 3'–5' DNA helicase belonging to the highly conserved RecQ family. In addition to a conventional DNA strand separation activity, BLM catalyzes both the disruption of non-B-form DNA, such as G-quadruplexes, and the branch migration of Holliday junctions. Here, we have characterized a new activity for BLM: the promotion of single-stranded DNA (ssDNA) annealing. This activity does not require Mg²⁺, is inhibited by ssDNA binding proteins and ATP, and is dependent on DNA length. Through analysis of various truncation mutants of BLM, we show that the C-terminal domain is essential for strand annealing and identify a 60 amino acid stretch of this domain as being important for both ssDNA binding and strand annealing. We present a model in which the ssDNA annealing activity of BLM facilitates its role in the processing of DNA intermediates that arise during repair of damaged replication forks.

INTRODUCTION

Bloom's syndrome (BS) is a rare genetic disorder associated with several abnormalities, including proportional dwarfism, sunlight sensitivity and a predisposition to cancers of most types. The gene mutated in BS, *BLM*, encodes a protein comprising 1417 amino acids that is a member of the highly conserved RecQ family (1,2). This family includes Sgs1p of *Saccharomyces cerevisiae*, Rqh1p of *Schizosaccharomyces pombe*, and the WRN, RECQ1, RECQ4 and RECQ5 proteins in humans. WRN and RECQ4 are defective in Werner's and Rothmund–Thomson syndromes, respectively, which are disorders not only associated with cancer predisposition but also with some features of premature aging (2). Where tested, all

RecQ family members are DNA helicases that translocate along DNA strands in the 3'–5' direction. A number of studies have shown that RecQ helicases unwind a wide variety of different oligonucleotide-based DNA substrates, including forked duplexes, four-way junctions modeling the Holliday junction, and simple 3'-tailed duplexes. Moreover, RecQ helicases can even unwind non-B-form DNA structures, such as G-quadruplexes (3–7).

RecQ helicases are defined by a highly conserved domain that contains seven signature motifs (hereafter referred to as the helicase domain) (2). These sequence motifs are also found, in a related form, in many other RNA or DNA helicases from different families. Outside of the helicase domain there is much less sequence similarity between RecQ family members. Nevertheless, there are two additional identifiable domains that are found in some, but not all, RecQ family proteins. One of these, the RQC (RecQ C-terminal) domain, is apparently unique to the RecQ family and is found in BLM. Recent X-ray crystallographic analysis of *Escherichia coli* RecQ protein indicates that the RQC domain forms a so-called winged-helix structure that is implicated in the binding of DNA (8). Indeed, a previous study showed that the RQC domain of WRN binds several DNA structures, including a forked duplex and a four-way junction (9). Interestingly, in some RecQ helicases, the RQC domain also seems to direct protein–protein interactions (10–12). A second sequence feature found in certain RecQ helicases, including BLM, is the HRDC (helicase and RNaseD C-terminal) domain (13). This domain is poorly conserved at the primary sequence level, but seemingly has a well-conserved structural fold comprising five α -helices and a number of basic residues that constitute a putative DNA binding surface (14). This domain is not unique to RecQ helicases, being present also in RNaseD homologs and, in a related form, in some DNA polymerases and recombinases. In those RecQ helicases where the RQC and HRDC domains are present, it is possible that interactions with different DNA substrates are influenced by either or both of these putative auxiliary DNA binding regions in the enzyme. Nevertheless, because some RecQ enzymes only

contain the helicase domain, and lack the RQC and HRDC domains, it seems highly likely that the helicase domain is both necessary and sufficient for at least some enzymatic activities. The functional role(s) of the RQC and HRDC domains can only be the subject of speculation at this stage, but a possible candidate is to extend the range of alternate DNA structures, such as G-quadruplexes or Holliday junctions, that can be recognized by a particular RecQ helicase.

Our studies of the RecQ helicase family are focused on the BLM protein. We have previously shown that BLM is a DNA structure-specific helicase that unwinds a wide variety of DNA molecules, although it is incapable of unwinding a blunt-ended DNA duplex (3,15). Nevertheless, it can disrupt a four-way junction modeling the Holliday junction recombination intermediate even if that substrate has blunt termini (15). Consistent with this activity being dependent upon branch migration, BLM has been shown to catalyze branch migration of bona fide Holliday junctions generated by the RecA recombinase (15). Here, we report a new activity for the BLM protein: the promotion of single-stranded DNA (ssDNA) annealing. We have characterized the biochemical properties of this strand annealing activity and have identified a short region of the C-terminal domain of BLM that is essential for this function. We provide evidence that strand annealing is influenced by ssDNA binding proteins, by nucleotide co-factors and by DNA length.

MATERIALS AND METHODS

Plasmids

Plasmids pJP71, pJP74 and pJP75, which were used for the expression of the truncated BLM variants, BLM642-1290, BLM642-1417 and BLM642-1350, respectively, were constructed as described previously (16). Briefly, the region of the *BLM* cDNA encoding residues 642–1290, 642–1350 or 642–1417 was amplified by PCR with primers introducing *NcoI* and *SapI* sites. The PCR product was digested with *NcoI* and *SapI*, and inserted between the *NcoI* and *SapI* sites of pTXB3 (NEB). Constructs for the expression of BLM213-1417 and BLM213-1267 have been described previously (17).

Protein purification

BLM, BLM213-1417 and BLM213-1267 were expressed as C-terminally hexahistidine-tagged proteins in the protease-deficient yeast strain JEL1 (*MAT α leu2 trp1 ura3-52 prb1-1122 pep4-3 his3::PGAL10-GAL4*) and were purified as described previously (18). BLM642-1290, BLM642-1350 and BLM642-1417 were produced as C-terminal fusion proteins with the Mxe-CBD affinity tag in the *E. coli* BL21-Codonplus-(DE3)-RIL strain (Stratagene) and were purified as described previously (16). Human replication protein A (RPA) was kindly provided by Dr A Vindigni. *E. coli* ssDNA binding protein (SSB) was purchased from USB. All concentrations of proteins are given in terms of moles of monomer.

DNA substrates

All oligonucleotides used in this study were purchased from Sigma Genosys and were purified by PAGE. X12-1

(5'-CGGGTCAACGTGGGCAAAGATGTCCTAGCAATGTAATCGTCTATGAGACG-3') and its complement X12-2 (5'-GACGCTGCCGAATTCTGGCTTGCTAGGACATCTTTGCCACGTTGACCCG-3') were used for the generation of the 31 bp forked duplex. DF-1 (5'-TGTAATCGTCTATGAGACGCGGGTCAACGTGGACATCTGCAAAGATGTCCTAGCAATGTAATCGTCTATGAGACG-3') and its complement DF-2 (5'-GACGCTGCCGAATTCTGGCTTGCTAGGACATCTTTGCAGATGTCCACGTTGACCCGGACGCTGCCGAATTCTGGC-3') were used for the generation of the twin-forked duplex. DS-50-1 (5'-GGCAAAGATGTCCTAGCAACGGGTCAACGTGGGCAAAGATGTCCTAGCAA-3') and its complement DS-50-2 (5'-TTGCTAGGACATCTTTGCCACGTTGACCCGTTGCTAGGACATCTTTGCC-3') were used for the generation of the 50 bp duplex; DS-31-1 (5'-CGGGTCAACGTGGGCAAAGATGTCCTAGCAA-3') and its complement DS-31-2 (5'-TTGCTAGGACATCTTTGCCACGTTGACCCG-3') were used for the generation of 31 bp duplex; DS-15-1 (5'-GGCAAAGATGTCCTA-3') and its complement DS-15-2 (5'-TAGGACATCTTTGCC-3') were used for the generation of the 15 bp duplex. X12-1, DF-1 DS-50-1, DS-31-1 and DS-15-1 were labeled at the 5' end using T4 polynucleotide kinase (NEB) and [γ -³²P]ATP. The forked duplex used in helicase assays was generated by the annealing of X12-1 and X12-2. X12-1 was 5'-³²P-labeled before annealing. All concentrations of DNA substrates are given in terms of moles of oligonucleotides.

Helicase assays

The 31 bp forked duplex was prepared as described previously (18). Reactions (20 μ l) were carried out at 37°C in buffer H (50 mM Tris-HCl, pH 7.5, 50 mM NaCl, 1 mM DTT and 0.1 mg/ml BSA) supplemented with 2 mM MgCl₂ and 2 mM ATP for 30 min in the presence of the indicated amounts of BLM and 1 nM of ³²P-end-labeled forked duplex substrate. Where indicated, SSB and RPA were added at a concentration of 60 and 3 nM, respectively. Reactions were stopped, and the samples were de-proteinized by the addition of stop buffer (50 mM EDTA, 1% SDS and 0.1 mg/ml proteinase K) and incubated at 37°C for 10 min. The reaction products were resolved on a native 10% (w/v) polyacrylamide gel (acrylamide to bis-acrylamide ratios 19:1) run in TBE at 30 mA per gel for 1 h at 4°C. The radiolabeled DNA was visualized using a PhosphorImager and the percentage DNA unwinding was quantified using ImageQuant software.

Strand annealing assays

DNA strand annealing activity was measured using fully or partially complementary oligonucleotides (at a concentration of 1 nM each), one of which was 5'-³²P-end-labeled. Reactions (20 μ l) were carried out in buffer H supplemented with 2 mM MgCl₂ unless otherwise indicated for 30 min at 37°C with the indicated concentrations of BLM. For time-course experiments, an 80 μ l reaction was initiated and 10 μ l aliquots were removed at defined time points. Reactions were stopped by the addition of stop buffer (50 mM EDTA, 1% SDS and 0.1 mg/ml of proteinase K) and incubated for 10 min at 37°C. Where indicated, RPA was added (0.75–48 nM) to the reaction. The reaction products were analyzed as described for the helicase assay.

Gel retardation assays

Radiolabeled oligonucleotide (1 nM) was incubated with BLM or its truncated derivatives in 50 mM triethanolamine, pH 7.5, 2 mM $MgCl_2$, 2 mM ATP γ S, 50 mM NaCl, 1 mM DTT and 0.1 μ g/ml BSA for 20 min at 37°C. Glutaraldehyde (0.25%) was then added and the reaction was incubated for a further 10 min at 37°C. The protein–DNA complexes were resolved on a 5% (w/v) native polyacrylamide gel (acrylamide to bis-acrylamide ratios 19:1) run in TBE at 150 V for 70 min at 4°C. The radiolabeled DNA was visualized using a PhosphorImager and the percentage ssDNA bound was quantified using ImageQuant software.

RESULTS

During an analysis of the DNA helicase activity of BLM, we observed that the appearance of the ssDNA product of unwinding followed an unusual pattern. The extent of ssDNA product formation increased with increasing enzyme concentration up to a point, beyond which the level of unwound product declined substantially. An example of such a pattern is shown in Figure 1a and quantified in Figure 1d for a forked DNA duplex substrate. In this particular case, the level of the ssDNA product of unwinding peaked in reactions containing ~ 10 nM BLM and then declined significantly until it was only marginally above background in reactions containing 80 nM BLM (Figure 1a and quantified in Figure 1d). One explanation for this phenomenon was that high concentrations of BLM were able to promote the re-annealing of the ssDNA products of the unwinding reaction. Consistent with this was the observation that addition of either *E. coli* SSB or human RPA, two unrelated ssDNA binding proteins, could overcome the apparent decline in helicase activity seen at high BLM concentrations (Figure 1b–d). Previously, it was shown that BLM helicase activity is stimulated by RPA (19), but not by SSB, making it unlikely that the similar effects of RPA and SSB shown in Figure 1 involved direct stimulation of BLM helicase activity.

To analyze this putative ssDNA annealing activity of BLM more directly, we incubated different concentrations of BLM with the two single-stranded 50mer oligonucleotides (each at 1 nM) that were utilized to create the forked duplex used in the experiment shown in Figure 1. One of these oligonucleotides was 5'-end-labeled to allow strand annealing to be monitored. We found that BLM promoted efficient annealing of the two oligonucleotides. Using BLM concentrations of ≥ 20 nM, $\sim 90\%$ of the labeled ssDNA was annealed to its complement (Figure 2a). Analysis of the kinetics of this reaction using a fixed BLM concentration (20 nM) indicated that 50% of the labeled oligonucleotide was annealed in <4 min (Figure 2b), using the reaction conditions described in Materials and Methods. Consistent with the notion that this reaction reflected genuine ssDNA annealing, addition of increasing concentrations of RPA progressively diminished the level of the annealed forked duplex product (Figure 2c). This confirmed that the ability of RPA to overcome the decline in helicase activity seen at high BLM concentrations (Figure 1c) was due to the inhibition of the ssDNA annealing activity of BLM.

BLM requires Mg^{2+} and ATP to catalyze DNA unwinding (18). We tested whether there was a similar co-factor

Figure 1. Inhibition of BLM helicase activity occurs at high protein concentrations, which is relieved by ssDNA binding proteins. (a) Unwinding of 1 nM of a 31 bp forked duplex catalyzed by different concentrations of BLM, as indicated above the lanes. (b) Unwinding of 1 nM of a 31 bp forked duplex catalyzed by BLM in the presence of 60 nM SSB or (c) in the presence of 3 nM RPA. In (a–c), the positions of the forked duplex and the ssDNA product of unwinding are indicated on the left. (d) Quantification of the helicase activity of BLM from the data in (a–c). All reactions were incubated for 30 min at 37°C.

requirement for the strand annealing function. As shown in Figure 3a, strand annealing promoted by BLM did not depend on the presence of Mg^{2+} . Indeed, the strand annealing activity was resistant to incubation with 50 mM EDTA (data not shown). Although there was a slight stimulation of strand annealing activity at a Mg^{2+} concentration of 1 mM, Mg^{2+} concentrations >4 mM caused a mild inhibition of the reaction. In marked contrast to the absolute requirement for ATP hydrolysis in DNA unwinding, increasing ATP concentrations strongly inhibited the DNA strand annealing reaction (Figure 3b). A similar, if slightly less dramatic, inhibition was seen with the poorly hydrolyzable ATP analog, ATP γ S. In contrast, concentrations of ADP up to 20 mM had no detectable inhibitory effect on the reaction (Figure 3b). Hence, the ssDNA annealing reaction promoted by BLM has different

Figure 2. BLM promotes annealing of ssDNA. (a) Effect of BLM concentration on the annealing of two ssDNA molecules to generate a forked duplex. Reactions were incubated for 30 min. (b) Time course of ssDNA annealing in reactions containing 20 nM BLM. (c) Effect of increasing concentrations of RPA on ssDNA annealing catalyzed by 10 nM BLM. In (a–c), the percentage of ssDNA annealed was quantified and the data are presented graphically on the right of the corresponding dataset.

Mg²⁺ and adenine nucleotide co-factor requirements from those needed to support BLM helicase activity.

Next, we asked whether oligonucleotide length influenced the efficiency of BLM-mediated strand annealing (Figure 4). We found that complementary 15mer oligonucleotides were not annealed to any detectable extent, while a 31mer pair could be annealed, albeit very inefficiently, requiring a BLM concentration of >40 nM. Increasing the oligonucleotide length to 50 nt substantially increased the extent of annealing, particularly in reactions containing a low BLM concentration (<20 nM). We then asked whether the annealing reaction required that the two oligonucleotides be fully complementary. To analyze this, we used two related oligonucleotide pairs. One pair comprised a 31mer complementary region and a non-complementary 19mer tail, which could form a forked partial duplex, and the other comprised the same 31mer complementary region flanked by two 19mer non-complementary regions that could form a twin-forked duplex (Figure 4a). Both oligonucleotide pairs could be annealed efficiently by BLM (Figure 4a and b), indicating that the annealing reaction does not require the oligonucleotides to be fully complementary, and that the complementary portion of the oligonucleotide need not be located at the ends of the DNA molecule.

Despite containing only 31 nt of complementary sequence, these oligonucleotides were annealed as efficiently as the fully complementary 50mers, and far more efficiently than the fully complementary 31mer pair (Figure 4a and b). These data indicate that, for a fixed length of complementary sequence, the overall length of the oligonucleotide strongly influences the efficiency of the annealing reaction.

Next, we addressed whether the differences in annealing efficiency noted above for different lengths of ssDNA were reflected in differences in the ability of BLM to form a stable complex with each DNA substrate. To achieve this, we used gel retardation assays with a 15mer, a 31mer and a 50mer single-stranded oligonucleotide. As shown in Figure 4c and d, BLM formed a stable complex with the 50mer and, to a much lesser extent, with the 31mer, but no complex with the 15mer could be detected. These data suggest that the DNA length-dependence of the ssDNA annealing reaction may be a reflection of the relative ability of BLM to bind stably to DNA molecules of different length.

In order to identify functional domains in BLM required for the ssDNA annealing reaction, we purified a series of truncated versions of BLM, which are shown diagrammatically in Figure 5. These variants all contain the central helicase and

Graph below shows quantification of the data.

RQC domains, but lack part or all of the N-terminal domain, and in some cases also part of the C-terminal domain. Initially, we analyzed whether strand annealing required the N- and C-terminal portions of BLM. A BLM variant lacking the N-terminal 212 amino acids (BLM213–1417) was proficient at strand annealing (Figure 6a and b), as indeed was BLM642–1417 that lacked the entire N-terminal domain (data not shown). In contrast, BLM213–1267 was barely able to catalyze strand annealing above the background level seen in the absence of BLM (Figure 6a and b) and showed a >10-fold reduced rate of strand annealing in comparison with BLM213–1417. This difference between these two BLM variants was specific for the strand annealing function of BLM, since the intrinsic helicase activity of each protein was comparable (Figure 6c). Importantly, these helicase assays were performed in the presence of SSB in order to prevent ssDNA annealing.

The results presented thus far would indicate that the C-terminal domain of BLM between residues 1267 and 1417

is important for its strand annealing function. Given that the entire N-terminal domain of BLM is dispensable for ssDNA annealing, we used BLM variants commencing at residue 642 to analyze whether the annealing function could be localized to a particular region of the C-terminal domain of BLM. We found that a protein truncated by only 67 C-terminal residues (BLM642–1350) could promote efficient strand annealing (Figure 6d). In contrast, removal of an additional 60 residues (to create BLM642–1290) generated a protein that had no detectable annealing activity (Figure 6d). The removal of residues 1291–1350 appear to specifically affect the strand annealing function of BLM since BLM642–1290 protein is an active helicase (16).

Since we had shown above that a correlation exists between DNA binding efficiency and an ability to promote annealing of different lengths of ssDNA, we next asked if those truncation mutants of BLM that were unable to promote annealing might have an alteration in their intrinsic ssDNA binding properties. Using gel retardation assays we found that, although there was no quantitative difference in the total amount of ssDNA bound by full-length BLM and its truncated derivatives, there was a clear qualitative difference in the nature of the retarded complexes when comparing strand annealing-proficient and -deficient variants. Using BLM, BLM213–1417, BLM642–1417 or BLM642–1350 at concentrations that promote efficient strand annealing, most of the retarded DNAs could not be resolved in the gel, indicative of the formation of large protein–DNA complexes (Figure 7). In contrast, the retarded species seen in reactions with the two strand annealing-defective variants, BLM213–1267 and BLM642–1290, were readily resolved within the gel (Figure 7). Taken together, these data indicate that the first 641 amino acids of BLM are not important for ssDNA binding or annealing, but that the 60 residues between positions 1290 and 1350 are essential for strand annealing and for the formation of higher-order protein–DNA complexes.

DISCUSSION

We report a new activity for the BLM helicase in showing that BLM promotes efficient annealing of complementary ssDNA molecules. This activity does not require Mg²⁺ or ATP, the co-factors essential for BLM to perform its helicase function. We have shown that significant DNA length dependence exists for the BLM strand annealing activity, which appears to derive from differences in the ability of BLM to form stable complexes with ssDNA of different lengths. Most interestingly, this length dependence does not require that the annealed strands be fully complementary. This may suggest that the mechanism by which BLM promotes ssDNA annealing is for it to bind non-specifically to the two ssDNA molecules and then to bring them into close proximity via protein–protein interactions between BLM molecules bound to the individual oligonucleotides. The length dependence may, therefore, reflect the number of BLM molecules that can bind simultaneously to each ssDNA molecule. Using different BLM variants, we found a strong correlation exists between ssDNA annealing activity and an ability to form higher-order protein–DNA complexes that were not resolved on polyacrylamide gels. In line with the comments above, we would propose that the formation of these large molecular

weight complexes is a function of the binding of multiple BLM molecules to each ssDNA oligonucleotide.

BLM may promote ssDNA annealing in a manner similar to that of the RAD52 recombination protein. RAD52 forms

oligomeric rings that bind ssDNA on their outer surface, and the annealing reaction requires that multiple rings engage their bound ssDNA in a large complex (20,21). BLM is oligomeric in solution, and previous studies have identified

4- and 6-fold symmetric ring structures that can form in the absence of DNA (22). However, the oligomeric state of the catalytically active form of BLM remains to be confirmed. Certain truncated forms of BLM are monomeric in solution and yet can still perform DNA unwinding (16), suggesting that the ability to form oligomers is not obligatory for helicase function. An interesting avenue for future research will be to address whether oligomerization of BLM is required for its ssDNA annealing function.

Recent data indicate that BLM is not alone among RecQ helicases in promoting strand annealing. Garcia *et al.* (23) showed that human RECQ5 β also possesses a DNA strand annealing activity that is strongly inhibited by RPA. However, we have data to indicate that such a strand annealing activity is not conserved in *E. coli* RecQ (C.F. Cheok, L. Wu and I.D. Hickson, unpublished data). This suggests that the annealing function is unlikely to be intrinsic to the highly conserved

(a) Gel retardation assays of BLM1–1417, BLM213–1417, BLM213–1267 (upper panel), BLM642–1417, BLM642–1350 and BLM642–1290 (lower panel) using a 50mer ssDNA oligonucleotide. The positions of the gel wells and of BLM–DNA complexes that could be resolved in the gel are indicated on the right. (b) Quantification of total ssDNA bound by BLM and its truncated derivatives. (c) Quantification of the ssDNA that was retarded in the gel wells. For clarity, the data are represented on two graphs in each case.

helicase and RQC domains, but rather is dictated by one of the poorly conserved N- or C-terminal regions that flank these domains in BLM. Consistent with this, the C-terminal domains of BLM and RecQ5 β are required for ssDNA annealing activity. Interestingly, the C-terminal domains of these two

proteins, however, show little sequence similarity. Notably, the RecQ5 β C-terminal domain lacks both the 60 amino acid region found in the C-terminal domain of BLM, which we have shown is essential for ssDNA annealing activity, and an HRDC domain, which in BLM lies adjacent to the critical

3940 *Nucleic Acids Research*, 2005, Vol. 33, No. 12

60 amino acid region. Moreover, there are obvious differences in the effects of nucleotide analogs on the respective activities of the two proteins. Most notably, the annealing activity of RECQ5 β is inhibited by ATP γ S, but not by ATP or ADP, whereas BLM is inhibited by both ATP γ S and ATP. While this manuscript was in preparation, we became aware of an electronic paper in press containing findings that overlap with those presented here. Machwe *et al.* (24) reported that RecQ family members, including BLM, promote DNA strand pairing as well as DNA unwinding. Our findings are in general agreement with those of Machwe *et al.* (24), except we did not find that BLM requires Mg²⁺ for its strand annealing activity. Moreover, in the present work, we have significantly extended our knowledge of the strand annealing function of BLM. In particular, we have mapped a domain in BLM vital for strand annealing activity and have defined structural features of the DNA substrates that are required for BLM to mediate this function.

An important issue to address is why should RecQ helicases catalyze apparently antagonistic reactions: DNA unwinding and ssDNA annealing? Although the precise cellular role of

any RecQ helicases is not fully elucidated, our previously published evidence indicates that BLM co-operates with topoisomerase III α to resolve DNA intermediates that arise during recombinational repair of replication forks (25). The ability of BLM to promote strand annealing of molecules with non-complementary ends indicates that BLM can promote strand annealing at internal sites in DNA and may not require DNA end recognition. One potential role for ssDNA annealing activity may be to promote the processing of Holliday junctions. BLM and topoisomerase III α together catalyze double Holliday junction dissolution (25), a process that requires the juxtaposition of two individual Holliday junctions. As two Holliday junctions are brought together in close proximity, the torsional stress generated by the convergence of the two junctions may be relieved by topoisomerases acting ahead of each migrating Holliday junction. The strand annealing activity of BLM acting on the strands behind each junction may function to overcome the torsional constraints imposed by two converging Holliday junctions (Figure 8a). Furthermore, as the two junctions are brought together in close proximity, steric hindrance may prevent either junction from being able

Figure 8. Models for the possible role of the strand annealing function of BLM in replication fork maintenance. (a) Branch migration model. Schematic representation of how torsional stress and steric hindrance may impede the convergence of two Holliday junctions by branch migration. The strand annealing activity of BLM acting on strands behind each junction may act to overcome these constraints and thereby facilitate the juxtaposition of two Holliday junctions. See text for details. (b) Fork regression model. Template strands are shown in black and nascent strands in red. The yellow triangle depicts a fork-blocking adduct on the leading strand template. See text for details.

to assume the necessary square planar configuration. Rather, each junction may assume the configuration in which the two duplexes are stacked, which is inhibitory to classical branch migration. Under these conditions, the ssDNA annealing activity of BLM may be required to promote an atypical form of Holliday junction branch migration in order to generate a hemicatenane, the presumed substrate for double Holliday junction dissolution. Our recent data indicate that the two strand annealing defective derivatives of BLM described here are also defective in catalyzing Holliday junction dissolution (26), although whether there is a mechanistic link between these two functions is unclear at this stage.

A second possible model (Figure 8b) for the role of the ssDNA annealing function specifically links BLM function with repair of damaged replication forks. Lesions on the leading strand template for DNA replication likely block fork progression. One proposal is that lesion bypass can occur via template switching in which the fork regresses via the annealing of the nascent strands to form a so-called chicken-foot structure (15,27). After extension of the leading strand and/or lesion removal, the regressed fork (a four-way junction) can be reversed by branch migration to re-set an active fork. We propose that BLM could catalyze both the fork regression step, by promoting annealing of the nascent strands, and the reversal of the regressed fork, using its helicase/branch migration function. In this way, BLM recruited to the arrested fork could promote repair and hence restoration of productive DNA replication. Clearly, further work is needed to identify whether these models have validity.

ACKNOWLEDGEMENTS

The authors thank Dr A.Vindigni for human RPA, Dr P. McHugh for helpful comments on the manuscript and members of the Genome Integrity Group for useful discussions and technical help. This work was supported by Cancer Research UK and the Swiss National Science Foundation. Funding to pay the Open Access publication charges for this article was provided by JISC. C.F.C. acknowledges the support of A*STAR (Singapore).

4 Conclusions and Perspectives

The human genome is constantly challenged with endogenous and exogenous DNA damage and requires a set of mechanisms to preserve its integrity. The human RECQ helicases seem to play an important role in resolution of aberrant structures that arise from different repair pathways and are likely to mediate other functions as well. The fact that there are five different RecQ family members in humans, whereas unicellular organisms only contain a sole RecQ helicase, points to the evolutionary split-up and extension of the RecQ-mediated processes. Many groups have contributed to unravelling the roles of the RecQ helicases but the DNA transactions mediated by these proteins are diverse and are not fully understood yet.

Yet, to elucidate the roles of the human RecQ helicases, different approaches must be combined. The observation that BLM and RECQ5 have non-redundant roles in suppressing is further supported by our finding that RECQ5 β cannot perform the DHJ dissolution in conjunction with TOPOIII α which is consistent with our finding that the HRDC domain of BLM - absent in RECQ5 β - is essential for efficient binding and unwinding of DHJs. As we have found that RECQ5 β exhibits strand-annealing activity in addition to its helicase activity, it may be that RECQ5 acts in the recovery of damaged replication forks by promoting fork regression, whereas BLM suppresses cross-overs that would appear from the repair of non-meiotic DHJs that arise from HR-dependent repair of daughter strand gaps formed during replications. To address this possibility, the next steps would be to knock down the protein levels of RECQ5 β in human cells and to characterise the phenotypic consequence with regard to sensitivities to DNA damaging agents and SCE frequency. A further evidence for the non-redundant roles of RECQ5 β and BLM could be obtained by knocking down RECQ5 β in BS cells and monitoring sensitivity to DNA damaging agents and the rate of SCEs. Furthermore, with experiments established for RecA and RecG to assay for fork-regression activity, RECQ5 β should be tested for its potential ability to regress forks.

Surprisingly, the functions of the human RecQ helicases are more global than only restricted to resolve aberrant DNA structure, as has been shown with RECQ4 that plays a role in replication initiation. The question arises if the role of RECQ4 in replication initiation is an evolutionarily acquired function, or if it is conserved in bacteria as well. Therefore, this aspect may be studied in *E. coli* and *S. cerevisiae*.

5 Acknowledgements

I'd like to thank Pavel for having given me the opportunity to do my PhD in his group and for guiding me along the way.

I'm grateful to Joe for all his support.

I thank everybody at IMCR, especially the friends I have found here.

Furthermore, I thank Steve West and Panos Soultanas for the collaborations and especially Ian Hickson for collaborations and discussions.

Last but not least, those without whom I would not have had the opportunity to grow and develop: my parents, family and friends. I thank them for all their support and love.

Place and date of birth, marital status, nationality

Born 23.10.1975 in Vevey, VD (Switzerland), single, swiss and spanish nationalities

Profession

Ph.D. student in biochemistry/molecular biology at the Institute for Molecular Cancer Research at the University of Zürich, Switzerland.

Awards

Charles Rodolphe Brupbacher Young Investigator's Award 2005

Languages

German	mother tongue	Spanish	good
English	accent free	Italian	good
Dutch	accent free	Portuguese	basic knowledge
French	very good	Swedish	basic knowledge

Education

1997-2002	Diploma studies of Biologie II (Biochemistry) at the Biocentre of the University of Basel, Switzerland.
1991-1997	High school, Gymnasium Interlaken Type C (focus on Mathematics and Physics), Interlaken BE.
1986-1991	Secondary school Unterseen, Unterseen BE
1982-1986	Primary school Unterseen, Unterseen BE

Scientific education

2002-	PhD thesis in the research group of Dr. P. Janscak at the Institute of Molecular Cancer Research (IMCR) of the University of Zürich, Switzerland on the biochemical and cellular functions of the human RECQ5 β helicase. Responsible member of faculty: Prof. Dr. J. Jiricny
-------	--

- 2001-2002 Diploma thesis in the group of Prof. Dr. T.A. Bickle in the department of Molecular Microbiology at the Biocentre, University of Basel, Switzerland under the supervision of Dr. P. Janscak with the title "Exploring the molecular mechanisms of the methyl-dependent restriction enzymes McrA and Mrr."

Other subject-related activities

- 2003- 2005 Translation of scientific articles for the official bulletin from English to German, interpreting and writing summaries of public talks on cancer for the website of the cancer league of the canton of Zürich. Contact person: C. de Capitani.
- Summer 2001 One month training at the Microbial Quality Control of the Laboratories of Dr. G. Bichsel AG in Unterseen, Switzerland. Adjustment of SOPs and room-classifications to comply with GMP and pharmaceutical regulations (Pharmakopö) under the supervision of Dr. M. Eisenhower.
